CORRESPONDENCE

G6PD IN *PLASMODIUM*-INFECTED ERYTHROCYTES

To the Editor:

Roth et al¹ have recently studied the reduction of oxidized glutathione (GSSG) in lysates prepared from normal and glucose-6-phosphate dehydrogenase (G6PD)-deficient human erythrocytes infected with *Plasmodium falciparum*. They found that the rates of GSSG reduction in infected G6PD-deficient lysates were elevated slightly, in comparison with uninfected cells, but were still substantially lower than rates in normal cells. They therefore concluded that the parasite-derived G6PD could not be considered a substitute for the normal host enzyme activity in alleviating the vulnerability (of host and parasite) to oxidant stress.

This interpretation is not, however, supported by the data, since it is based on the implicit assumption that the *in vivo* rate of GSSG reduction is related directly to the G6PD activity. In fact, the rate of GSSG reduction in normal intact cells is nearly linearly dependent on the activity of hexokinase²; G6PD activity is therefore present in considerable excess with a control coefficient estimated to be 0.006, compared to a value of 0.995 for hexokinase.² Consequently, the rates of GSSG reduction measured by Roth et al¹ (in diluted lysates supplied with NADP⁺ and not glucose but glucose 6-phosphate (G6P) at concentrations sufficient to saturate G6PD) are not an indication of the cells' ability to withstand oxidative stress, but rather are analogous to a coupled enzymic assay for measuring G6PD activity. The effect of bypassing the physiologically rate-limiting hexokinase reaction is demonstrated by comparison of the normal rate of production of reduced glutathione (GSH) found in intact cells (22 $\mu\text{mol/h/g Hb}^2$) with the value of 785 $\mu\text{mol/h/g Hb}$ found by Roth et al, in diluted lysates.

Comparison of the GSSG reduction rate measured in freeze-thaw lysates (supplied with G6P and NADP⁺) of normal and G6PD-deficient cells is therefore misleading, since the rate determined in

normal cells is not attained *in vivo* with the natural substrate, glucose. Sonicate-lysates (supplemented with niacinamide and NADP⁺ and supplied with glucose) would be a better system for studying comparative rates, since these preparations show rates of GSH production identical to those in intact cell suspensions.² Even these comparisons would have to be treated with caution, however, since hemolysis abolishes any heterogeneous distribution of G6PD activity which may be present in suspensions of intact cells.

Indeed, it is possible that sonicate-lysates of infected G6PD Mediterranean cells (supplied with glucose) would show rates of GSH production not much lower than uninfected normal lysates, since the infected G6PD-deficient lysates¹ had GSH production rates (29 to 83 $\mu\text{mol/h/g Hb}$), with G6P as substrate, that were higher than normal cells² supplied with glucose as substrate (22 $\mu\text{mol/h/g Hb}$). If this were the case, however, it would not be sufficient evidence to conclude that the parasite enzyme alleviated the vulnerability of host and parasite to oxidant stress, since physical separation of G6PD (presumably located within the parasite) from GSSG in the erythrocyte cytosol may prevent this. The homogenization caused by hemolysis should therefore be avoided when investigating whether the parasite enzyme can replace the deficient host enzyme in protecting against oxidative stress; the only unequivocal way to approach this problem is therefore to determine the extent of GSH regeneration in intact parasitized G6PD-deficient cells, following oxidation of GSH with, for example, *t*-butyl hydroperoxide (as in ref 2).

cyte hexose-monophosphate shunt under conditions of oxidative stress: A study using NMR spectroscopy, a kinetic isotope effect, a reconstituted system and computer simulation. *Eur J Biochem* 150:371, 1985

To the Editor:

Thorburn and Kuchel have correctly pointed out some limitations in our recent studies on *P. falciparum*-infected normal and G6PD deficient red cell lysates.¹ However, we find that their interpretation of the data does not change our conclusion concerning the poor capacity of the infected G6PD-deficient red cell to resist oxidative stress. They also have likely overestimated the ability of their computer model,² based entirely on the study of normal uninfected red cells, to deal with the complexities of G6PD deficiency or malaria-infected red cells, especially simultaneously.

It has been known for some time that G6PD and pentose shunt activities in normal, unstressed red cells are well below maximal levels, which can be obtained *in vitro* by adjusting a number of variables in intact red cells as well as in lysates.³ The writers are correct in asserting that our assay of pentose shunt activity overestimates the *in vivo* rate—particularly in unstressed, uninfected red cells. We deliberately framed our study to operate at near-maximal G6PD activity so that at least the upper possible limit of a response

to an oxidative stress could be estimated. We reasoned that if even these maximal activities were not adequate for dealing with oxidative stress, then it would be unlikely that intact cells with lower G6PD activity could perform differently. Thorburn and Kuchel do concede that perhaps G6PD Mediterranean red cells when infected can reduce as much oxidized glutathione (GSSG) as normal, uninfected and unstressed red cells. However, when normal red cells are stressed, they can augment pentose shunt activity at least ten- to fifteenfold.⁴ Merely bringing pentose shunt activity up to the normal, unstressed resting level is not likely to be sufficient for dealing with oxidative stress. Thus, we see no essential conflict between our interpretation of the data and that of Thorburn and Kuchel.

The problem of performing studies on intact cells v lysates (or homogenate/sonicates) is not new in biochemistry. The relatively new possibility of using nuclear magnetic resonance (NMR) for intact cell studies represents an advance in this field and certainly deserves exploration. However, unequivocal results are not likely to be forthcoming, because it will be difficult to tell which compartment is yielding a signal for glutathione or other metabolites.

Furthermore, if the molecular exchange among the compartments is rapid compared with the NMR relaxation times being measured, then an average signal from all compartments may be seen and nothing more. This would not be very different from extracting all the metabolite of interest from a homogenate/lysate of all compartments and measuring it by a more classical technique. The problem of compartmentalization in parasitized red cells alluded to by Thorburn and Kuchel is indeed a difficult one which deserves consideration. How many compartments are there? Should we consider the red cell membrane, red cell cytoplasm, parasitophorous vacuole membrane, the parasitophorous vacuole itself, parasite membrane, parasite cytoplasm, parasite nucleus, and the parasite food vacuole each as separate compartments? Are the Maurer's clefts yet another compartment? Can NMR compartments be distinct from anatomical ones? Such considerations seem to confound bold assertions that there is an "unequivocal way" to approach these problems. Nevertheless, we have also performed intact cell experiments using acetylphenylhydrazine (APH) as the oxidant stress.³ We observed enhanced reduced glutathione stability when infected red cells were challenged with APH and compared to uninfected normal red cells challenged in the same way. When glucose was omitted from the incubation medium, reduced glutathione disappeared more rapidly from infected cells than from uninfected ones. This finding suggests that metabolic communication between the parasite and red cell cytoplasm does occur. The use of *t*-butylhydroperoxide does produce a rapid loss of reduced glutathione, but also kills the parasites (Roth et al, unpublished observation). Thus, in an NMR experiment as suggested by Thorburn and Kuchel, using this reagent, one would be detecting signals from the red cell cytoplasm and a compartment containing the cadaver of a malaria parasite. While this experiment might be interesting, it would hardly be unequivocal. (APH also kills parasites, but more slowly.)

We come next to the computer model of Thorburn and Kuchel which states that hexokinase activity alone controls the activity of the pentose shunt. This model, derived from studies of the red cells of a single normal individual, did not include data from red cells in which G6PD activity approaches zero; nor does it consider an

infected red cell containing a separate parasite hexokinase⁶ (whose kinetic characteristics are unknown) as well as a completely different pathway (based on parasite-derived glutamate dehydrogenase) for the generation of NADPH (and hence GSSG reduction), which is totally independent of hexokinase. In such a complex system, it is unlikely that a linear relationship between human host cell hexokinase activity and GSSG reduction will apply. The concept that the G6PD-dependent pathway of GSSG reduction is much smaller than indicated by studies of dilute lysates also emphasizes the possible importance of the glutamate dehydrogenase pathway which, although small in infected lysates, could account for as much as 50% of the total GSSG reducing capacity in vivo.

Finally, we note the work of Morelli et al⁷ which Thorburn and Kuchel cite in their paper² in support of their interpretation of the pivotal role of hexokinase in controlling the pentose shunt. Morelli et al state: "... in G6PD deficient erythrocytes, unlike in the normal cells, hexokinase no longer plays any rate-limiting role on the glucose utilization through the HMS [hexose monophosphate shunt] which is rather controlled by the low levels of G6PD activity." We are unable to explain why Thorburn and Kuchel cite this reference when it supports their conclusions, but ignore it when it does not.

In summary, we believe that there is no serious conflict in the interpretation of our data, which are a first attempt at characterizing a difficult problem. We thank Thorburn and Kuchel for pointing out limitations and other interpretations of our experiments as well as for suggesting interesting further experiments both with lysates and intact cells. The suggested experiments have much merit although by themselves, they are unlikely to lead to an "unequivocal" interpretation in such a complex system as the parasitized human erythrocyte.

MIXED CHIMERISM AND RESTRICTION FRAGMENT LENGTH POLYMORPHISM

To the Editor:

Blazar and coauthors¹ describe the use of restriction fragment length polymorphisms (RFLP) of DNA fragments for the investigation of chimerism and origin of leukemic relapse following allogeneic bone marrow transplantation (BMT). Analysis of RFLP provides more complete information about chimerism than cytogenetics, because all nucleated cells are evaluated whether proliferating or

not. Unlike red cell typing, analysis of RFLP allows more insight into chimerism and is independent of transfusions. In our opinion the most important questions are (1) the origin of leukemic relapse from host or donor cells, and (2) the significance of mixed chimerism as a prognostic factor of impending relapse.

However, the data of analysis given by the authors are weak. For example, in patient No. 10, analysis of the recipient's normal and leukemic hemopoiesis was not performed prior to BMT. The conclu-

sion of leukemic relapse in host type cells rests entirely on the occurrence of a single new band during relapse (ref 1, Fig 2).

Fig 3 and the respective legend¹ are confusing: the bands of lanes 3 and 5 are different, but the samples (MNC) are taken from the same day, ie, day 15 after BMT.

Demonstration of mixed chimerism depends on the sensitivity of the RFLP technique, but the sensitivity was tested only for probe pDP 34. The sensitivity may vary with the amount of material available. We have used isoenzymes for studying chimerism and could detect 1% to 2% of 10^5 cells plotted.

In an informative case we could demonstrate leukemic relapse of host type restricted to granulopoiesis together with a minority of mature granulocytes of host type.² In this patient previous analyses

had revealed complete chimerism. In another case we found mixed chimerism persisting for more than a year without leukemic relapse. Therefore, we believe that mixed chimerism after BMT is not necessarily a sign of poor prognosis, nor is complete chimerism a sign of good prognosis regarding leukemic relapse. In support of this hypothesis further data need to be collected.

To the Editor:

We agree with Drs Mittermüller and Kolb that two of the more important questions relating to leukemia relapse are the donor or host origin of the leukemia relapse and the significance of mixed chimerism in predicting relapse in patients with underlying malignancies. Therefore, we have been prospectively performing DNA analysis on allogeneic transplantation patients in our institution since June 1984. We have now studied 95 donor-recipient pairs pretransplant and have data available on 65 of these patients posttransplant. DNA analysis has permitted us to document definitively the donor or host origin of patients who have experienced leukemia relapse or posttransplant lymphomas¹ and the degree of engraftment of patients who are at higher risk for potential graft failure,^{2,3} as well as to analyze the kinetics of lineage-specific engraftment. The purpose of our report⁴ was to demonstrate the comparative utility of this technique as opposed to speculating on the questions addressed by Drs Mittermüller and Kolb.

Since we are now screening all allogeneic donor and recipient pairs pretransplant for donor-specific and host-specific polymorphisms, we have been able to demonstrate conclusively the donor or host origin of patients undergoing leukemia relapse. This will eliminate the type of retrospective analysis which was conducted in our first series of experiments (ref 4, Fig 2).

As a means of determining graft stability, we have used the prior samples as internal controls for the quantitation of the most recently obtained specimen whenever possible. In Fig 3,⁴ lanes 3 and 5 were generated from the same DNA sample obtained 15 days posttransplant. Lanes 1 through 3 were generated from the same autoradiogram,

while lanes 4 through 7 were generated from a second autoradiogram. The densitometric scanings of the original autoradiograms were remarkably similar, although, as described,⁴ there can be many factors contributing to differences in the accuracy of the final autoradiographic analysis.

The sensitivity of DNA analysis has been consistently reported to be 1% to 5%, regardless of the probe utilized. In our study, we used the probe pDP 34 to determine the sensitivity of this technique. However, similar results have been obtained by two other groups of investigators: one group⁵ used a probe that hybridized to a portion of the immunoglobulin gene; the other group⁶ used probe D14S1. Each of the groups has reported sensitivity of 1% to 5%. In addition, we have compared enzymatic analysis to DNA analysis for patients who have inherited metabolic disorders. In contrast to DNA typing, enzyme typing was more likely to be influenced by post-BMT variables affecting their expression.⁷

We have also observed several patients with persisting Philadelphia chromosome-positive cells who have remained in clinical remission. We concur that mixed chimerism after transplant is not necessarily a sign of poor prognosis but rather indicates that incomplete myeloablation of either normal cell populations or malignant clones probably has occurred. We anticipate that the data generated by these types of studies will provide useful information as to the frequency of this occurrence.

LACK OF EFFECT OF HEPARIN ON FACTOR XIa

To the Editor:

A report by Beeler et al in the May 1986 issue of *Blood*¹ claims to provide evidence that "plasma concentrations of antithrombin III completely saturated with heparin would become the dominant factor in the inhibition of factor XIa." This statement appears to differ from our summary also published in *Blood*² in October 1982 that "heparin, at concentrations used in clinical practice, does not accelerate the inactivation of human factor XIa by antithrombin III." Therefore, we decided to analyze the possible source of the differences in the two reports.

First, it is important to consider the concentrations of heparin used in both studies. The experiment of Beeler et al, in a purified system, used a single concentration of heparin, 5.88×10^{-6} mol/L, which, based on their specific activity of 350 USP U/mg and a mol wt of 27,000 daltons, yields a concentration of 14.4 USP U/mL. This "saturating" concentration is 40-fold higher than the average pharmacologic concentration of 0.35 USP U/mL found during clinical anticoagulation and fivefold higher than that employed in cardiopulmonary bypass. In our study, we used a range of concentrations from 1 to 30 U/mL in a purified system using both amidolytic and coagulant assays (not esterolytic as stated by Beeler et al). We found no difference in the rate of inactivation of factor XIa by antithrombin III at 1 U/mL heparin in the purified systems. Unlike Beeler et al, we extended our study into plasma systems and were able to confirm the lack of effect of 1 U/mL heparin on the rate of inactivation of factor XIa.

Second, we also examined the suprapharmacologic concentration of heparin used in the study of Beeler et al. We documented a maximal 4-fold increase in the rate of inactivation. In our study, at 23 °C, which assumed the plasma ATIII concentration to be 4.7 μ mol/L, the inactivation rate constant without heparin was 5.4×10^3 mol/L⁻¹min⁻¹ and 2.7×10^4 mol/L⁻¹min⁻¹ at 30 U/mL heparin. When these experiments were performed at 37 °C (unpublished results) using the plasma antithrombin concentration reported by Beeler et al of 2.5 μ mol/L for plasma concentration, the second order rate constants were 3.1×10^4 mol/L⁻¹min⁻¹ without heparin and 1.51×10^5 mol/L⁻¹min⁻¹ with 30 U/mL heparin. Therefore, our data in the presence of heparin is in good agreement with that of Beeler et al, whose calculated second order rate constant is 1.59×10^5 mol/L⁻¹min⁻¹. However their second order rate constant in the absence of heparin of 4.7×10^3 mol/L⁻¹min⁻¹ is only 15% of our value, explaining the apparent 40-fold increase.

Several problems in their experimental procedures may explain their lower value. No controls are presented in their paper for the loss of activity with factor XIa alone, or factor XIa with heparin. Indeed the loss of activity in the absence of heparin is stated to be approximately 50% of the rate constant making its accuracy suspect.

Furthermore, contact proteins demonstrate biphasic loss of activity upon contact with plastic³ making a single time-point correction factor in error. In the experiments performed by Beeler et al, single reactions for each point were used which may lead to greater error in calculations of the actual concentrations of initial activity. When first order kinetics are performed by subsampling from a single reaction vessel, as in our study, one can extrapolate to time zero in order to determine the actual initial concentration of enzyme in the reaction mixture. Moreover, pseudo-first-order reaction rate constants are not accurately determined unless the reaction has undergone at least one half-life, which was not shown in the paper of Beeler et al. Further, our values for the inactivation rate of factor XIa by antithrombin III without heparin in purified systems⁴ agree closely with those observed in plasma. Thus, it appears that the differences observed by Beeler et al stem from an underestimation of the inactivation rate in the absence of heparin.

Our experiments in both purified and plasma systems at pharmacological concentrations of heparin lead us to reassert our conclusion that α_1 -antitrypsin, not antithrombin III, is the major inhibitor of factor XIa in plasma. Our previous study, in collaboration with Dr Rosenberg,⁵ indicates that heparin had minimal effect in accelerating the inactivation of plasma kallikrein by antithrombin III in purified systems and no effect in plasma. A recent study in *Blood* from our laboratory⁶ indicates that heparin had little effect on factor XIIa in purified systems and in plasma. Finally, in a recent study presented at the American Society of Hematology in December 1986 in collaboration with Dr Peter Harpel, we showed evidence for activation of the contact system during clinical cardiopulmonary bypass in the presence of 5 U/mL heparin. Thus, we find that heparin and antithrombin III, although critically important for thrombin, factor Xa, and possibly factor IXa, play little role in the regulation of the contact system of blood coagulation.

McNeely and Griffith⁷ demonstrated that in the presence or absence of 0.5 U/mL of heparin, the amounts of radiolabeled factor IX cleaved in plasma after exposure to glass (contact activation), phospholipid, and calcium were identical. They conclude, in agreement with us, that heparin has no significant effect on the reaction rate between antithrombin III and the enzymes preceding factor IX in the intrinsic pathway.

To the Editor:

Colman and Scott have provided a detailed critique of our studies. We have previously pointed out numerous experimental problems in their recent investigations of the kinetics of factor XIa-antithrombin-heparin interactions and do not find it necessary to repeat them here.¹ In any case, one of our pictures is more compelling than repeating a myriad of arcane kinetic arguments. Western blot analyses of our reaction mixtures graphically show the generation of large amounts of factor XIa-antithrombin complex in the presence of optimal levels of heparin but no visible interaction product in the absence of the mucopolysaccharide (Figure 2¹). Unpublished data indicate that the factor XIa-antithrombin complex generated in the absence of heparin would have been detected if it were present at as little as 2.5% to 5.0% of the final concentration of factor XIa-antithrombin interaction product formed in the presence of mucopolysaccharide. Thus, heparin must be augmenting the antithrombin-dependent neutralization of factor XIa by 20- to 40-fold. We cannot even claim any great originality for this particular result since Kurachi and Davie² reported a similar finding employing SDS-PAGE and have reached similar conclusions about the magnitude of the mucopolysaccharide-induced augmentation of factor XIa-antithrombin interactions. Based upon the available evidence, we believe that our estimate of the acceleration of factor XIa-antithrombin interactions by heparin (40-fold) is more likely to be correct than that of Scott and Colman (two- to fourfold). Indeed, the original studies of this phenomenon conducted by us more than a decade ago³ appear to be valid.

The effects of heparin therapy on factor XIa-antithrombin interactions were not considered within our publication.¹ However, we did suggest that antithrombin fully complexed with the endogenous

anticoagulant active heparan sulfate of the endothelium could represent a critical biologic mechanism for neutralizing factor XIa within the circulation. We believe this to be the case because of the dramatic acceleration of factor XIa inhibition by antithrombin in the presence of saturating levels of mucopolysaccharide; the unusually strong dependence of the velocity of factor XIa neutralization on selective concentration of antithrombin by mucopolysaccharide on the surface of endothelial cells [see rate equation for factor XIa neutralization¹], and the known relatively slow actions of other protease inhibitors within the blood. This scenario might be quite different during heparin therapy when only a small fraction of antithrombin is complexed by the anticoagulant and when the protease inhibitor might not be concentrated within a small region of the vascular tree. We hope that our results lead other investigators to examine the intriguing possibility that the endogenous heparan sulfate-antithrombin system is critically involved in regulating the in vivo activity of the contact phase of the coagulation mechanism rather than generate endless disputes over the exact extent of inhibition of factor XIa by antithrombin in the presence of heparin.

DISCRIMINANT ANALYSIS FOR PROBABILITY OF HEMOPHILIA A CARRIERSHIP

To the Editor:

Green et al¹ recently reported a multilaboratory study on hemophilia A carrier testing. They concluded that a linear discriminant function of Factor VIII coagulant activity (F.VIII:C) and von Willebrand factor antigen (VWF:Ag) adjusted for age and ABO blood type provided the best discrimination and that the ratio F.VIII:C/VWF:Ag gave poor results. Our experience has been different. Using a similar analysis, we find the ratio method to be just as accurate and much easier for clinical use.

We have used both a bivariate linear discriminant function, prepared as described by Elston et al,² and a univariate discriminator, the natural logarithm of the ratio F.VIII:C/VWF:Ag, as described elsewhere.³ The ratio has several advantages. The well-documented⁴ effects of age on F.VIII:C and VWF:Ag are approximately equal, and the ratio shows no significant regression on age in

groups of 49 carriers, 81 normal women, and 100 blood donors (unpublished observation). Also, no significant difference in F.VIII:C/VWF:Ag between Type O and non-O women was reported by McCallum et al.⁵ This was confirmed in our blood donor sample. Therefore, neither age nor ABO blood type need be introduced into the discriminant if the F.VIII:C/VWF:Ag ratio is used. Green et al¹ apparently used age-adjusted levels in calculating their ratios.

Table 1 shows our experience with discriminant analysis using the ratio method. Carrier and normal subjects are divided into those used in calculating the discriminant (Group I) and those tested later (Group II). The discrimination is slightly better than that reported by Green et al,¹ although our sample size is considerably smaller. We found fewer misclassifications with the ratio (6.9%) than with the bivariate discriminant produced from the same data (9.2%, data not shown). Average odds favoring carriership were 30:1 in the carriers

Table 1. Use of the Ratio of F.VIII:C/VWF:Ag for Carrier Detection

	Misclassifications	
	No.	%
Carriers		
Group I	3/23	13.0
Group II	3/26	11.5
total carriers	6/49	12.2
Normals		
Group I	2/38	5.3
Group II	1/43	2.3
total normals	3/81	3.7
All subjects	9/130	6.9

and 1:5.9 in the normals; however, we question the accuracy of this method for comparing the discriminants. We too have noted unusual results at the extreme ends of the distributions with both bivariate and univariate discriminants. In particular, subjects with very high F.VIII:C/VWF:Ag may fall in the upper tail of the noncarrier

distribution, where f_n and f_c are both very small numbers, occasionally producing falsely high likelihood ratios. This appears to happen more often with the ratio method. In using the discriminants clinically, these aberrant results are easily recognized. In the data of Green et al,¹ the average odds and misclassification rates for normals using ratios might be lower if such results were removed or modified.

Use of a ratio of F.VIII:C/VWF:Ag to assess probability of carriership is both conceptually and computationally simpler. It produces a low level of misclassification and by avoiding some of the statistical complexity could allow more laboratories to establish their own discriminants. It would be interesting to see whether unadjusted ratios could be used to produce a simple "universal" discriminant.

To the Editor:

Miller and Aledort suggest that the greater accuracy, in our sample of 336 carriers and 137 normal women,¹ of a universal linear discriminant in comparison to a universal ratio discriminant may be due to the presence of a few individuals with falsely high likelihood ratios. That such is not the case is evident from scatterplots of the odds for carriership for the two discriminants (Figures 1C and 1D¹). In these plots, subjects who are assigned higher odds for carriership by the linear discriminant appear as points below the diagonal line, and vice versa; it is then clear that the linear discriminant assigns higher odds to carriers, and lower odds to normals, than does the ratio, for a substantial majority of subjects. Similar results were seen when nonadjusted ratios were used (data not shown). Odds greater than 100:1 were trimmed to 100:1 in these plots, as well as in computing the average odds for carriership (Table 5¹).

We feel that this graphic method for comparing the two discriminants is superior to the misclassification rate used by Miller and Aledort, since the genetic counselor is interested in the odds rather than a classification per se, and since the misclassification rate may be unduly influenced by the behavior of the discriminant for individuals having odds near 1:1 (for whom the discriminant is of little use). In any case, in our study the linear discriminant also had the lower misclassification rate (Table 5¹). Miller and Aledort used a linear discriminant prepared as described by Elston et al,² which does not include a correction for ABO blood type. This correction should be included, since it improves discrimination for some subjects.¹

The method outlined in the appendix to our paper reduces calculation of the odds for carriership to a few simple arithmetic manipulations of the data, which can easily be programmed on a programmable hand calculator. No statistical software is required. Ease of use is thus essentially the same for the two discriminants, and should have no bearing on a laboratory's choice between them. We know of at least two laboratories not participating in the original study that have implemented our method, with satisfactory results.

GRANULATION IN ALL BLASTS

To the Editor:

I read with interest the detailed report of Fradera and colleagues¹ that discussed the diagnostic confusion caused by the presence of variably sized azurophilic granules in the cytoplasm of blasts of acute lymphoblastic leukemia (ALL) and described the cytochemical and ultrastructural characteristics of these inclusions. Contrary to the authors' impression, the occurrence of such granules in ALL is neither uncommon nor unreported.²⁻⁴ Moreover, several ultrastructurally different organelles can produce inclusions mimicking the azurophilic granules of early myeloid cells at the light microscopic level, and different granules have different cytochemical properties. Anomalous azurophilic granules occurring in blasts and immature cells of lymphoid leukemias can be roughly divided as follows:

Crystalline: Elongated crystals that can either represent immunoprotein, usually in an envelope of rough endoplasmic reticulum, or nonimmunoglobulin structures with a regular periodicity (often 55 Å), have been reported in chronic lymphocytic leukemia⁵ and prolymphocytic leukemia.⁶ The inclusions containing ribosomal material are pyroninophilic, whereas other crystalline inclusions contain acid hydrolases and phosphatases suggesting lysosomal origin. Crystals rich in immunoglobulin often may fail to react with Romanowsky stains, producing a clear, rectangular to rhomboidal space in the cytoplasm of the blast or immature lymphoid cell.^{7,8}

Ribosomal Variants: Malignant lymphoid cells of both chronic⁹ and acute¹⁰ lymphocytic leukemias have been reported to contain variably sized azurophilic inclusions that ultrastructurally resemble the lamellar-ribosomal complex of the hairy cell. Anday⁹ further

reports that granules resembling the lamellar-ribosomal complex possess pyroninophilia abolished by ribonuclease pretreatment.

Lysosomal/mitochondrial: Several authors describe azurophilic granules in blasts of lymphoid origin that have been proven by electron microscopy (EM) to originate from lysosomes, mitochondria, or combinations of both organelles.^{11,12} The cytochemical reactions of such granules vary, but most often they are similar to those seen in the cells of the patient of Fradera and colleagues,¹ containing nonspecific acetate or butyrate esterase—usually fluoride resistant—acid phosphatase, and glucuronidase. Many also react to period acid-Schiff (PAS).^{4,11} Rarely, granules of this sort contain lipid and react to Sudan Black B, creating major diagnostic confusion.¹³ They do not react with granulocytic specific lysosomal stains such as myeloperoxidase and ASD chloroacetate esterase.

The appearance of such anomalous azurophilic granules in ALL blasts is not unusual, as they were found in ~10% of the new ALL patients studied at St Jude's.⁴ Hematologists and pathologists should not diagnose French-American-British (FAB) M1 acute leukemia on the morphological appearance alone, especially in a clinical context more suggestive of ALL. Cytochemical confirmation of the granulocytic origin of the leukemic cells is essential. Given the occasional report of sudanophilic granules in ALL blasts,^{4,13} the stains used should be granulocyte enzyme-specific, such as myeloperoxidase or ASD chloroacetate esterase. Only such testing can avoid the diagnostic problem so well illustrated by Fradera and colleagues.¹

To the Editor:

We read with interest the comments by Dr Richard Savage and would like to clarify one point and perhaps raise others.

When we decided to study and publish our case with the abnormal granules¹ we were convinced, and still are, that we were reporting a most unusual finding. Unfortunately, Dr Savage missed the point of

our report. We did not report a case of ALL with azurophilic granulation. Indeed, we were most impressed by the fact that the granules were actually not azurophilic. This was clearly described in the light microscopy section of our report (p 407) and can be observed in the color photomicrographs accompanying the article. The granules were described as dark purple, and we believe that the data as presented illustrated the fact that they appeared more like

inclusions than granules, as is generally observed in hematopoietic cells.

In addition, Dr Savage errs when he states that the cytochemical findings in our case were similar to those reported by others^{2,3} who studied azurophilic granules in ALL blasts. Although we agree that the cytochemical evaluations of the blasts containing the azurophilic granules reported by others are similar, our findings were not the same. In our case, the granules gave negative results with all stains tested. Dr Savage's confusion probably arises from the fact that we also described the cytochemical evaluation of the lymphoblasts of our case. These studies revealed an unusual reaction obtained in the lymphoblasts of our patient with the α -naphthyl acetate stain illustrated in Fig 2 of our paper. These studies, however, should not be confused with those of the abnormal granules that were the main subject of our publication.

Dr Savage's letter raises other interesting points in regard to azurophilic granules. We were surprised to read his statement: "The presence of such anomalous azurophilic granules in ALL blasts is not unusual, as they are found in ~10% of the new ALL patients studied at St Jude's Hospital." This information was based on a report by Stein and colleagues² describing a detailed evaluation of five cases of granulated ALL in which the authors screened 66 cases of ALL for the presence of prominent azurophilic intracytoplasmic granules. In our experience with 140 adult patients with ALL in the last 10 years, this has been an extremely rare finding in adults and as such was mentioned in the now classic paper by Bennett and co-workers⁵ in which the French-American-British (FAB) classification was described in 1976 and which included both pediatric and adult patients. Furthermore, in an even more detailed definition of the morphological criteria important in the classification of ALL by

Bennett and co-workers⁵ in 1979, the presence of azurophilic granules was not mentioned. Nevertheless, if the more common presence of these azurophilic granules, as reported by Stein and co-workers² could be corroborated by other pediatric centers specialized in the study of leukemia, this could lead to a revision of the now accepted FAB classification with the recognition of granular ALL as a subtype of ALL, type L₂. This also raises the possibility that if azurophilic granulation in ALL blasts has indeed increased during recent years, a larger number of cases should be available to allow a better characterization of such granules, including utilization of cytogenetic and electron microscopic studies to determine if they represent a finding of clinical relevance in a homogeneous group of patients.

In summary, Dr Savage's observations have raised new perspectives in the study of morphological findings that may be occurring in growing numbers of pediatric patients with ALL in whom azurophilic granules are apparently more common, and corroborate that large, nonazurophilic granulation in lymphoblasts, such as the ones described by us, are indeed a very rare and unique finding. Our case probably represents one of the very few cases, if not the only well-documented case, of such an entity.

ERRATUM

In the article entitled "Absence of Tubular Structures and Immunolabeling for von Willebrand Factor in the Platelet α -Granules From Porcine von Willebrand Disease" by Cramer et al, which appeared in the September issue (Volume 68, Number 3, pages 774-778), the diameters of the granule-associated tubules and of the microtubules should be read in Angströms and not in nanometers (200 Å and 250 Å, respectively).

ANNOUNCEMENTS

HOUSTON SOCIETY OF CLINICAL PATHOLOGISTS

Houston, TX
April 25, 1987

Slide seminar on lymphomas and leukemias presented by Robert Collins, MD, and John Bennett, MD.

For further information, contact: James J. Butler, MD, Department of Pathology, Box 85, M.D. Anderson Hospital, Houston, TX 77030.

AMERICAN SOCIETY OF HEMATOLOGY

Spring Symposium on Hematopoietic Growth Factors

Durham, North Carolina
April 20-21, 1987

The American Society of Hematology is holding a two-day symposium on hematopoietic growth factors sponsored by Burroughs Wellcome Company, to be held at the Searle Center in Durham, North Carolina on April 20 and 21, 1987. The topics will include the molecular biology of the hematopoietic growth factors, their biological actions, and the results of in vivo studies with these molecules in experimental animals and humans. Among the participants will be Steven Clark, Malcolm Moore, David Golde, Judith Gasson, Ken Kaushansky, Gordon Wong, Peter Quesenberry, John Adamson, and Colin Sieff.

Additional information and details of the program are available through Dr Wendell F. Rosse, PO Box 3934, Duke University Medical Center, Durham, NC 27710. Individuals interested in submitting abstracts or poster presentations, or preregistering are encouraged to do so by March 1, 1987. Maximum registration: 200.

GEORGETOWN UNIVERSITY MEDICAL CENTER, WASHINGTON, DC "BONE MARROW TRANSPLANTATION: PROGRESS AND PROBLEMS"

Washington, DC
March 28, 1987

SHORT COURSE IN MEDICAL & EXPERIMENTAL MAMMALIAN GENETICS

July 20-31, 1986
Bar Harbor, Maine

Conducted by The Jackson Laboratory and Johns Hopkins University School of Medicine. Lectures covering the entire field are supplemented by methodologic workshops in cytogenetics, biochemical screening, linkage analysis, and molecular genetics, as well as demonstrations of mouse mutants and problems in clinical genetics. Held at The Jackson Laboratory. *Inquiries and applications should be made to:* Victor A. McKusick, MD, 292 Carnegie Bldg, Johns Hopkins Hospital, 600 N Wolfe St, Baltimore, MD 21205; or to Thomas H. Roderick, PhD, c/o Training & Education Office, The Jackson Laboratory, Bar Harbor, ME 04609.

**LEUKEMIA SOCIETY OF AMERICA
THIRD ANNUAL NATIONAL SYMPOSIUM**

**Town and Country Hotel, San Diego, CA
March 18-21, 1987**

Designed to focus on the latest advances and techniques in research and treatment of leukemias and lymphomas, the program will address current information and rapidly developing new approaches and programs in studies of the disease. Emphasis will be upon the application of basic science and its relation to clinical practice. The meeting is geared to physicians, nurses, allied professionals, fellows-in-training, residents, and students with major interest and involvement in leukemia and related disorders. The course is accredited for CME by the AACME. It meets the criteria for 17 credits in Category I towards the Physician's Recognition of the AMA. Registered nurses will qualify for 20.7 contact hours of continuing education through the LSA's provider accreditation for continuing education for registered nurses.

There will be a keynote address on "Chromosomes, Genes, and Leukemia" by Peter C. Nowell, MD; Stohlman Memorial Scholar papers; posters; and five minisymposia, dealing with: biological characteristics of clinical trial designs; molecular genetics; application of molecular probes; antimyeloid monoclonal antibodies; and cellular response to growth factors. There will also be daily group breakfasts and an awards banquet. Registration fee: physicians: \$100; nurses, fellows-in-training, residents, and students: \$60. Fees are due by March 11, 1987.

For registration and additional information, contact: LSA Medical Conference, c/o Bostrom Corporation, 435 N Michigan Ave, Suite 1717, Chicago, IL 60611. Telephone: (312) 644-0828.

SIGMA DIAGNOSTICS NEW HEMATOLOGY TOOLS ARE BLUE, RED, PURPLE AND ALL SHADES IN-BETWEEN. BECAUSE PEOPLE LIKE TO SEE THINGS DIFFERENTLY.

ACCUSTAINS™ FOR HEMATOLOGY

ACCUSTAIN is a term now applied to a new group of Sigma Diagnostics liquid stains that exhibit superior features. ACCUSTAINS for hematology include special formulations of Wright Stain and Giemsa Stain for manual and automated applications. For the first time, guesswork has been removed from use of Wright Stain and Giemsa Stain. These materials are prepared as precisely defined mixtures of xanthenes and thiazine dyes. Their precision manufacture virtually eliminates lot-to-lot variation. The ACCUSTAINS for hematology exhibit consistent Romanowsky behavior; requiring no adjustment of staining times each time a new batch of material is used. This sets ACCUSTAINS apart from materials offered by other manufacturers.

Fastest manual reagents with superior staining characteristics.
Reproducible results.
No lot-to-lot reagent variation.
Comparable manual and automated staining.
No reagent precipitation problems.
Unusually stable reagents.
Defined reagent composition.
Stable stain solutions for automation.
Stain components manufactured by Sigma Diagnostics assuring maximum quality control.

NEW MONOCLONAL ANTIBODIES

The new group of monoclonal antibodies is the first of a growing line of products designed to identify hematopoietic differentiation antigens. These highly purified markers are carefully examined for specificity using established neoplastic tissue culture lines.

HEMATOLOGY	PROCEDURE NUMBER

For Alexander, who can't produce enough antibodies to fight infection...

Young or old, patients without sufficient levels of antibodies face overwhelming infection... and they urgently need help. Aggressive IGIV treatment with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens, in just minutes.

For patients like Alexander, GAMIMUNE® N provides premium IGIV: immune globulin that contains at least 98% pure gamma globulin¹; unmodified "native" IgG with immunologic activity of normal plasma; and documented *in vitro* inactivation of HTLV-III virus* during fractionation from plasma to final gamma globulin.²

When patients don't have enough antibodies to fight infection, like Alexander, it's nice to know that GAMIMUNE® N does.

Aggressive IGIV treatment in immunodeficiency syndromes.
Also for both chronic and acute ITP in children and adults.

GAMIMUNE® N
Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

No *more* expensive than other IGIV therapy, GAMIMUNE® N may, in some cases, be *less* expensive. A contributing factor is that GAMIMUNE® N is a convenient, ready-to-use, liquid formulation that saves valuable pharmacy time.

No premium cost
for TODAY'S
IGIV.

*The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1×10^5 TCID₅₀ (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID₅₀ (Tissue Culture Infectious Doses) reduction of HTLV-III.²

Please see following page for brief summary of prescribing information.

GAMIMUNE[®] N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune[®] N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune[®] N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The *in vivo* half-life of Gamimune[®] N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N is 16.5 mEq/L (~0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune[®] N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune[®] N at a dose of 150 mg/kg body weight, following a dose of 400 mg/kg body weight in 37 patients; there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune[®] N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune[®] N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune[®] N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune[®] N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune[®] N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune[®] N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune[®] N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune[®] N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune[®] N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune[®] N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune[®] N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PLA¹ alloimmune antibody with platelet anti PLA¹ specificity) also responded to treatment with Gamimune[®] N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N should be considered, in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune[®] N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune[®] N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune[®] N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune[®] N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune[®] N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune[®] N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune[®] N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune[®] N. It is not known whether Gamimune[®] N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune[®] N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune[®] N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune[®] N. Symptoms reported with Gamimune[®] N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N at the infusion site was reported in some cases.

In further studies of Gamimune[®] N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune[®] N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune[®] N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune[®] N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune[®] N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune[®] N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune[®] N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune[®] N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune[®] N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune[®] N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes, if well tolerated, the rate may be gradually increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

HEMATOLOGY REVIEWS AND COMMUNICATIONS

An International Journal

Editor: **Stuart Roath**, University Haematology, General Hospital,
Tremona Road, Southampton SO9 4XY, UK
Co-Editor: **Milton Corn**, Department of Medicine, Georgetown University
Hospital, 3800 Reservoir Road N.W., Washington, DC 20007, USA

AIMS AND SCOPE

The Reviews section carries reviews on all hematological and hematological/oncological topics. These will usually be in depth studies of a selected area, shorter reviews (often grouped by field), or even substantial longer reviews covering a complete issue. Each issue of the journal may contain review articles written at the invitation of the editor. Authors wishing to submit a review article for consideration should submit a summary to the editor or co-editor before commencing detailed work on the manuscript. The Communications section publishes research communications for rapid publication. This will facilitate the quickest possible presentation of newly acquired research data. Papers on both clinical and laboratory based data are welcomed. Only in exceptional cases would case reports qualify for inclusion.

EDITORIAL BOARD:

Twenty years ago, leukemia killed enough people to fill Madison Square Garden.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

For more information, including the free booklet "What Everyone Should Know About Leukemia," write to: Leukemia Society of America, 733 Third Ave., New York, New York 10017.

leukemia[®]
society of america, inc.

We're closing in on a killer.

FACULTY POSITIONS: The Hematopathology Program, Division of Laboratory Medicine, M. D. Anderson Hospital and Tumor Institute has three faculty positions open for two M.D.'s and a Ph.D. The M.D. should have training and research experience in hematologic pathology. The Ph.D. should have a record of productive research in hematopoietic neoplasia. The successful applicants will be expected to develop independent and collaborative research in hematopoietic neoplasia. Preference will be given to individuals who have a background in molecular biology. One M.D. position is at the academic rank of Faculty Associate. Academic rank is commensurate with qualifications and experience for the other two positions. Send curriculum vitae, names of three references, and a statement of research interests to: Sanford A. Stass, M.D., Division of Laboratory Medicine, Box 73, M. D. Anderson Hospital and Tumor Institute, 1515 Holcombe Blvd., Houston, Texas 77030. The University of Texas System Cancer Center is an Equal Opportunity/Affirmative Action Employer.

Faculty Positions	xxxvii
UNIVERSITY OF WISCONSIN, MILWAUKEE	
Assistant/Associate Professor	xxxviii

Asst/Assoc Professor, tenure track, Ph.D. in Hematology or related area. Department of Health Sciences seeks faculty with clinical/research interests for expanding undergrad/grad curriculum in clinical laboratory sciences. Preference will be given to applicants with extensive clinical laboratory experience and/or certification. Letter of application/curriculum vitae must be received by March 1, 1987. Submit applications to: Chairperson, Search and Screen, Medical Technology Program, Dept of Health Sciences, Univ of Wisconsin-Milwaukee, P.O. Box 413, Milw. WI. 53201, (414) 963-5324. UWM is EOAAE.

**COOLEY'S
ANEMIA FOUNDATION, INC.
RESEARCH FELLOWSHIPS**

The Cooley's Anemia Foundation, Inc., invites applications for fellowships to both postdoctoral fellows and junior faculty members interested in the field of Cooley's anemia with stipends of up to \$15,000. The deadline for receipt of applications is April 1, 1987. Awards will be made by June 15, 1987, and funding will begin July 1, 1987, for one year with the possibility of renewal for a second year.

For application forms and further information, write: Mr. Michael C. DiFilippo, National Executive Director, Cooley's Anemia Foundation, Inc., 105 East 22nd Street, Suite 911, New York, New York 10010. Telephone: (212) 598-0911.

There is a road.

Many cancer patients need transportation to and from treatments. That's why the American Cancer Society has formed groups of volunteers across the United States who give a few hours of their time each month to drive them. The road to recovery can be a long and difficult one, but it can be that much easier when there are friends who can help along the way.

American Cancer Society

More people have survived cancer than
now live in the City of Los Angeles.
We are winning.

REACH FOR SUPERIOR RESULTS

*Becton Dickinson
Monoclonal Reagents*

Leading research laboratories throughout the world select Becton Dickinson Leu monoclonal reagents for choice, quality, and convenience.

We offer the industry's largest selection of monoclonal antibodies to human leucocytes, human immunoglobulins, complement receptors, and mouse leucocytes as well as a full line of second-step reagents.

New products include: Simultest™ reagents for single-step, two-color immunofluorescence using unique combinations of conjugated monoclonal antibodies; and I-PATH™, a series

of more than 25 products specifically formulated for tissue immunopathology.

Each Becton Dickinson reagent is characterized by extensive FACS™ analysis and tested by multiple methods to ensure superior quality.

And all Becton Dickinson reagents are supplied in solution, ready to use.

Becton Dickinson Leu monoclonal reagents. Superior quality for superior results.

For a current product listing, contact your Becton Dickinson Immunocytometry Systems Representative, or call us at the number below.

Consider: Thousands of Patients

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

Burroughs Wellcome Co.
3030 Cornwallis Road
Research Triangle Park, NC 27709

Patients Rescued

WELLCOVORIN[®] TABLETS (leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.¹

¹Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

WELLCOVORIN® TABLETS (leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B₁₂. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below $5 \times 10^{-8} M$.^{1,2}

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e., trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.^{3,4,5}

Wellcome | Research Triangle Park, NC 27709

You can help us raise the colorectal cancer cure rate.

"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkpoint Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces
cancer alone.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

SPECIAL DEPARTMENTS

Correspondence	974
Erratum	976
Announcements	977
Information for Contributors	xxi, xxii

Effective January 1, 1987, all manuscripts submitted to **BLOOD** and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

All manuscripts submitted for consideration for publication in **BLOOD** should be sent to: John W. Adamson, MD, Editor, **BLOOD**, University District Building—Room 410, 1107 NE 45th St, Seattle, WA 98105. Telephone: (206) 545-8080.

Please note that a processing fee of \$50.00 must accompany each manuscript submitted for publication in **BLOOD**.

The American Society of Hematology certifies that the continuing medical education offering provided by *BLOOD, The Journal of The American Society of Hematology*, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

Radiogenic mucositis or herpes simplex?

See answer under flap.

Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

ZOVIRAX[®] I.V.
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

When the problem begins with a virus,
end it with an antiviral.

The diagnostic
challenge in
immunocompromised
patients...

Please see following page for brief summary of prescribing information.

ZOVIRAX® I.V. (acyclovir sodium) STERILE POWDER / I.V. INFUSION

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M² every 8 hours (750 mg/M²/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.^{1,2,3}

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.⁴

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.⁵

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.⁶

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M²) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used

in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax (acyclovir sodium) sterile powder is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INfections in IMMUNOCOMPROMISED PATIENTS — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M² at a constant rate over 1 hour, every 8 hours (750 mg/M²/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M ²)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

Model #B5061
with CO₂ Auto-Zero System

Next to in vivo, Heraeus provides the most perfect growth environment.

The Heraeus B5061 and B5060 Series CO₂/O₂ Incubators provide incomparable performance and features for extremely accurate replication of in vivo environments. The B5061 CO₂/O₂ includes an exclusive self-adjusting Auto-Zero System, permitting precise automatic recalibration of the CO₂ content from 0 to 20%. The O₂ Incubators provide even greater accuracy and control for differing pO₂ conditions, and can be adjusted between 3 and 95%.

Both the B5061 and B5060 offer modular plug-in electronics, constant 95% RH, choice of acid-resistant stainless steel or germicidal and fungicidal copper inner walls, and easily removable, non-tilting, stainless steel shelves.

Model #B5060

Temperature control is within $\pm 0.1^\circ\text{C}$. Heating elements are located outside of the inner chamber, preventing the formation of condensation on the glass doors and chamber ceiling. This eliminates the risk of condensate dropping onto the cultures.

West Germany's finest Incubator manufacturing technology assures the high quality performance of Heraeus Incubators.

Before considering the purchase of a CO₂ or O₂ Incubator, you should find out more about the Heraeus B5061 and B5060 Series, as well as our other fine Incubation Systems and accessories. For a copy of our brochure, call or write today.

Next to in vivo, Heraeus.

Today's IGV. Don't settle for less.

For immunodeficiency syndromes: aggressive protection against infection

Patients without sufficient levels of antibodies face overwhelming infection, and they need help. Infusion with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens... in just minutes.

For both chronic and acute ITP in children and adults: rapid elevation of platelet levels

GAMIMUNE® N may initiate a therapeutic increase in platelets in both children and adults with idiopathic thrombocytopenic purpura (ITP).^{1*} Treatment with GAMIMUNE® N has enabled some ITP patients to undergo major surgery.¹

IGIV that's at least 98% pure gamma globulin

Cutter's fractionation method (Cohn-Oncley 6 & 9) contains all the necessary steps to produce high purity immune globulin. GAMIMUNE® N contains no foreign contaminants, no detectable levels of protein aggregates or vasoactive enzymes.² With GAMIMUNE® N you get what you expect... IGV containing at least 98% pure gamma globulin.¹

GAMIMUNE® N
Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

Documented in vitro inactivation of HTLV-III virus[‡]

[‡]The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.³

"Native" IGIV

GAMIMUNE®N is manufactured without chemical modification. This means GAMIMUNE®N antibodies maintain normal opsonization capacity, have a normal distribution of IgG subgroups and provide the immunologic activity of normal plasma.¹

Artist's interpretation of HTLV-III virus.

Today's simple, economical IGIV: the only ready-to-use liquid

Dose for dose, GAMIMUNE®N saves money by eliminating valuable reconstitution time in the pharmacy. Gram for gram of protein, GAMIMUNE®N is affordable; there is no premium price for TODAY'S IGIV.

Artist's interpretation of blood platelets.

*It is not possible to predict which patients with ITP will respond to therapy.

¹In patients who respond to therapy, a rise in platelet count is generally rapid (within 1 to 5 days), transient (most often lasting from several days to several weeks) and should not be considered curative.

From the original IGIV, today's IGIV...it offers more

Please see following page for brief summary of prescribing information.

GAMIMUNE[®] N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune[®] N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune[®] N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The *in vivo* half-life of Gamimune[®] N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N is 16.5 mEq/L (~0.3 mEq/g protein); a dose of 150-400 mg/kg (3.8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune[®] N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune[®] N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune[®] N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune[®] N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune[®] N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune[®] N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune[®] N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune[®] N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune[®] N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune[®] N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune[®] N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune[®] N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune[®] N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PLA¹ alloimmune antibody with platelet anti PLA¹ specificity) also responded to treatment with Gamimune[®] N at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune[®] N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune[®] N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune[®] N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune[®] N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune[®] N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune[®] N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune[®] N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune[®] N. It is not known whether Gamimune[®] N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune[®] N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune[®] N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune[®] N. Symptoms reported with Gamimune[®] N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N at the infusion site was reported in some cases.

In further studies of Gamimune[®] N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune[®] N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune[®] N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune[®] N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgias, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune[®] N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune[®] N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune[®] N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune[®] N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune[®] N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune[®] N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes, if well tolerated, the rate may be gradually increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

The first troche treatment for oropharyngeal candidiasis.

Before treatment.¹

After treatment with MYCELEX Troche.¹

High clinical cure* rates.

A clinical cure rate of 96% was achieved in one randomized double-blind trial² in which MYCELEX Troche was administered to patients with oropharyngeal candidiasis. Other investigators have concluded that MYCELEX Troche "is highly effective treatment for chronic oral candidiasis."³

Dramatic improvement in symptoms.

Patients attain a high degree of relief at the end of therapy, as evidenced by the dramatic decrease in severity of glossitis, patches, perleche, pain, and other clinical signs and symptoms of thrush.⁴

Good patient acceptance, minimal side effects.

With MYCELEX Troche, messy suspensions and lengthy swishing are things of the past. MYCELEX Troche has a pleasant, slightly sweet taste. And an entire day's therapy—5 troches—can easily be carried in pocket or purse.

Based on a study of 52 episodes of oropharyngeal candidiasis, the investigators stated: "We believe that the troche form of clotrimazole...in the treatment of thrush in any patient population...is both effective and safe."^{2†}

*Clinical cure is defined as absence of signs and symptoms of the disease.

†See adjacent page for summary of prescribing information, including contraindications and adverse reactions.

Mycelex[®] Troche

(clotrimazole) 10 mg

The only troche for oropharyngeal candidiasis.

MYCELEX® (clotrimazole) TROCHE

Indications and Usage: Mycelex Troches are indicated for the local treatment of oropharyngeal candidiasis. The diagnosis should be confirmed by a KOH smear and/or culture prior to treatment.

Contraindications: Mycelex Troches are contraindicated in patients who are hypersensitive to any of the components.

Warning: Mycelex Troches are not indicated for the treatment of systemic mycoses.

Precautions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials. In most cases the elevations were minimal and it was often impossible to distinguish effects of clotrimazole from those of other therapy and the underlying disease (malignancy in most cases). Periodic assessment of hepatic function is advisable particularly in patients with preexisting hepatic impairment.

Since patients must be instructed to allow each troche to dissolve slowly in the mouth in order to achieve maximum effect of the medication, they must be of such an age and physical and/or mental condition to comprehend such instructions.

Carcinogenesis: An 18-month dosing study with clotrimazole in rats has not revealed any carcinogenic effect.

Usage in Pregnancy: Pregnancy Category C. Clotrimazole has been shown to be embryotoxic in rats and mice when given in doses 100 times the adult human dose (in mg/kg), possibly secondary to maternal toxicity. The drug was not teratogenic in mice, rabbits, and rats when given in doses up to 200, 180, and 100 times the human dose.

Clotrimazole given orally to mice from nine weeks before mating through weaning at a dose 120 times the human dose was associated with impairment of mating, decreased number of viable young, and decreased survival to weaning. No effects were observed at 60 times the human dose. When the drug was given to rats during a similar time period at 50 times the human dose, there was a slight decrease in the number of pups per litter and decreased pup viability.

There are no adequate and well-controlled studies in pregnant women. Clotrimazole troches should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Pediatric Use: Safety and effectiveness of clotrimazole in children below the age of three years have not been established; therefore, its use in such patients is not recommended.

Adverse Reactions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials (see Precautions section).

Nausea and vomiting was reported in about one in 20 patients.

Dosage and Administration: Mycelex Troches are administered only as a lozenge that must be dissolved slowly in the mouth. The recommended dose is one troche five times a day for 14 consecutive days. Only limited data are available on the safety and effectiveness of the clotrimazole troche after prolonged administration; therefore, therapy should be limited to short-term use, if possible.

How Supplied: Mycelex Troches—white, discoid, uncoated tablets are supplied in bottles of 70 and 140. Each tablet will be identified with the following: Miles 095.

Store below 86°F (30°C), avoid freezing.

NOW AVAILABLE
IN STERILE POWDER FOR INJECTION

FROM ROCHE RESEARCH

Introducing a new modality in cancer therapy

Leading the way in biotherapeutics

Copyright ©1987 by Hoffmann-La Roche Inc. All rights reserved.

a breakthrough in hairy cell leukemia

- ☐ Effective in all stages of the disease.
- ☐ Statistically increased survival compared to a historical control group.
- ☐ Normalizes peripheral blood elements.
- ☐ Improves quality of life.
- ☐ Dramatically decreases the need for red blood cell and platelet transfusions.
- ☐ Virtually eliminates life-threatening opportunistic infections after several months of therapy.
- ☐ Ready-to-use injectable solution—no mixing or reconstitution.
- ☐ Also available in sterile powder for injection with diluent for reconstitution.
- ☐ SC or IM injection and fixed dosing permit administration without weight or body surface area calculation in home, office or institution.
- ☐ Caution patients not to change brands of Interferon without medical consultation, as a change in dosage may result.
- ☐ Common initial side effects, such as fever, chills, myalgia, headache and fatigue, are self-limiting and generally manageable. Myelosuppression, which can occur early in the treatment course, warrants close clinical and laboratory observation and is usually alleviated by dose reduction or temporary discontinuation of drug. Persistent fatigue is found to be less troublesome with *p.m.* or *h.s.* administration.

Injectable Solution—
3 million IU vial (3 million IU/mL) —
18 million IU vial (3 million IU/0.5 mL)

Sterile Powder for Injection—
18 million IU and 3 mL diluent for reconstitution (3 million IU/0.5 mL)

SC/IM
ROFERON[®]-A
Interferon^{BRAND OF} alfa-2a, recombinant/Roche

a promise fulfilled

Before prescribing, please see complete product information on following pages.

ROFERON®-A (Interferon alfa-2a, recombinant/Roche)

in their early to midfetal period (days 22 to 70 of gestation). A late-fetal period study (days 79 to 100 of gestation) is in progress and as yet there have been no reports of any increased rate of abortion.

Usage in Pregnancy: Safe use in human pregnancy has not been established. Therefore, Roferon-A should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. Information from primate studies showed dose-related menstrual irregularities and an increased incidence of spontaneous abortions. Decreases in serum estradiol and progesterone concentrations have been reported in women treated with human leukocyte interferon.⁴ Therefore, fertile women should not receive Roferon-A unless they are using effective contraception during the therapy period.

Male fertility and teratologic evaluations have yielded no significant adverse effects to date.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from Roferon-A, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children under 18 years of age have not been established.

ADVERSE REACTIONS: The following data on adverse reactions are based on the subcutaneous or intramuscular administration of Roferon-A as a single agent for the treatment of 63 patients with hairy cell leukemia during investigational trials in the United States.

Flu-like syndromes consisting of fatigue (89%), fever (98%), chills (64%), myalgias (73%) and headache (71%) occurred in the majority of patients and tended to diminish with continuing therapy. Other side effects such as anorexia (46%), nausea (32%), emesis (10%), diarrhea (29%), dizziness (21%), rash (18%), change in taste (13%), dryness or inflammation of the oropharynx (16%), dry skin or pruritus (13%) and weight loss (14%) were observed with moderate frequency. Less commonly, diaphoresis (8%), paresthesias (6%), numbness (6%), partial alopecia (8%), reactivation of herpes labialis (8%), transient impotence (6%) and arthralgias (5%) were also observed. Rarely (<3%), central nervous system effects including decreased mental status, depression, visual disturbances, sleep disturbances and nervousness, as well as cardiac adverse events, including hypertension, chest pain, arrhythmias and palpitations, were reported. Adverse experiences which occurred rarely and may have been related to underlying disease, included epistaxis, bleeding gums, ecchymosis and petechiae. Miscellaneous adverse events, such as night sweats, urticaria, conjunctivitis and inflammation at the site of injection, were also rarely observed. Roferon-A has also been evaluated for the treatment of many other types of cancer under investigational trials in the United States. These studies generally utilized higher doses (12 to 50 million IU/m²). All of the previously described adverse reactions which occurred in patients with hairy cell leukemia were also observed in patients receiving higher doses. The incidence of most adverse reactions was similar between the two groups, but tended to be more severe in patients who received higher doses of Roferon-A. Some additional adverse effects which occurred in these patients included confusion (10%), hypotension (6%), lethargy (3%) and edema (3%). Adverse experiences occurring in less than 1% of these patients and observed only in patients with malignancies other than hairy cell leukemia are as follows: **Gastrointestinal**—abdominal fullness, hypermotility and hepatitis; **Central Nervous System**—gait disturbance, poor coordination, hallucinations, syncope, seizures, encephalopathy, psychomotor retardation, coma, stroke, transient ischemic attacks, aphasia, aphonia, dysarthria, dysphasia, forgetfulness, amnesia, sedation, apathy, anxiety, emotional lability, irritability, hyperactivity, involuntary movements, claustrophobia and loss of libido; **Peripheral Nervous System**—muscle contractions; **Cardiovascular**—congestive heart failure, pulmonary edema, myocardial infarction, Raynaud's phenomenon and hot flashes; **Pulmonary**—bronchospasm and tachypnea; **Miscellaneous**—excessive salivation and flushing of skin. **Abnormal Laboratory Test Values:** The percentage of patients with hairy cell leukemia or with other types of malignancies who experienced a significant abnormal laboratory test value at least once during their treatment is shown in the following table:

ABNORMAL LABORATORY TEST VALUES

	Hairy Cell Leukemia (n = 63)	Overall Safety Summary* (n = 1019)
Hematologic		
Leukopenia	59%	69%
Neutropenia	39%	58%
Thrombocytopenia	42%	42%
Decreased Hemoglobin	36%	6.3%
Decreased Hematocrit	43%	12.5%
Mean Time to Nadir		
WBC	38 days	22 days
Platelets	19 days	17 days
Hepatic		
SGOT	47%	78%
Alkaline Phosphatase	18%	48%
LDH	12%	47%
Bilirubin	1.6%	31%
Renal/Urinary		
BUN	2%	10%
Serum Creatinine	3%	10%
Uric Acid†	6%	15%
Proteinuria‡	10%	25%
Other Chemistry Tests		
Hypocalcemia	10%	51%
Elevated Serum Glucose‡	33%	39%
Elevated Serum Phosphorus	2%	17%

*Patients with hairy cell leukemia are included in this overall summary.

†The majority of abnormal uric acid values and proteinuria were of minimal severity. Since these abnormalities are commonly observed in patients with advanced malignancy, it is difficult to ascertain their relationship to Roferon-A treatment.

‡Random glucose determination.

Neutralizing antibodies to Roferon-A were detected in approximately 27% of all patients (3.4% for patients with hairy cell leukemia). No clinical sequelae of their presence have been documented thus far. Antibodies to human leukocyte interferon may occur spontaneously in certain clinical conditions (cancer, systemic

ROFERON®-A (Interferon alfa-2a, recombinant/Roche)

lupus erythematosus, herpes zoster) in patients who have never received exogenous interferon.⁵

DOSAGE AND ADMINISTRATION: Hairy Cell Leukemia—The induction dose of Roferon-A is 3 million IU daily for 16 to 24 weeks, administered as a subcutaneous or intramuscular injection. Subcutaneous administration is particularly advisable for, but not limited to, thrombocytopenic patients (platelet count < 50,000) or for patients at risk for bleeding. The recommended maintenance dose is 3 million IU, three times per week. Dosage reduction by one-half or withholding of individual doses may be needed when severe adverse reactions occur. The use of doses higher than 3 million IU is not recommended. Patients should be treated for approximately six months before the physician determines whether to continue therapy in patients who respond or discontinue therapy in patients who did not respond. Patients with hairy cell leukemia have been treated for up to 20 consecutive months. The optimal duration of treatment for this disease has not been determined.

If severe reactions occur, dosage should be modified (50% reduction) or therapy should be temporarily discontinued until the adverse reactions abate. The need for dosage reduction should take into account the effects of prior X-ray therapy or chemotherapy that may have compromised bone marrow reserve. The minimum effective dose of Roferon-A has not been established.

The subcutaneous or intramuscular routes of administration should be used. Subcutaneous administration is particularly suggested for, but not limited to, patients who are thrombocytopenic (platelet count < 50,000) or who are at risk for bleeding.

Injectable Solution:

3 million IU Roferon-A per vial—Each 1 mL contains 3 million IU of Interferon alfa-2a, recombinant/Roche, 9 mg sodium chloride, 5 mg Albumin (Human) and 3 mg phenol as a preservative.

18 million IU Roferon-A per vial—Each 1 mL contains 6 million IU of Interferon alfa-2a, recombinant/Roche, 9 mg sodium chloride, 5 mg Albumin (Human) and 3 mg phenol as a preservative. Each 0.5 mL contains 3 million IU of Interferon alfa-2a, recombinant/Roche.

Sterile Powder for Injection:

18 million IU Roferon-A per vial—Reconstitute with 3 mL diluent and swirl gently to dissolve. When reconstituted with Diluent for Roferon-A, each 1 mL of reconstituted solution contains 6 million IU Interferon alfa-2a, recombinant/Roche, 9 mg sodium chloride, 5 mg Albumin (Human) and 3 mg phenol as a preservative. Each 0.5 mL contains 3 million IU of Interferon alfa-2a, recombinant/Roche. Once the powder is reconstituted, it must be used within thirty (30) days.

The sterile powder and its accompanying diluent, the reconstituted solution and the injectable solution should be stored in the refrigerator at 36° to 46°F (2° to 8°C). Do not freeze or shake.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

HOW SUPPLIED:

Roferon-A Injectable Solution: Vials containing 3 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/mL). Boxes of 10 (NDC 0004-1987-01).

Roferon-A Injectable Solution: Vials containing 18 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/0.5 mL). Boxes of 1 (NDC 0004-1988-09).

Roferon-A Sterile Powder for Injection: Vials containing 18 million IU Interferon alfa-2a, recombinant/Roche, with accompanying diluent. Boxes of 1 (NDC 0004-1993-09).

Announcing a new international review journal. FREE sample copies available on request.

Edited by
I Chanarin and David W Golde

Haematology is such a large and rapidly developing field that it is no longer possible for any haematologist to keep abreast of current findings by reading the primary research journals.

Blood Reviews, the new international review journal;

- provides an authoritative and readable update on topics of interest to all haematologists
- is intended for those engaged in haematology at a clinical and laboratory level, as well as for researchers and those in training;
- offers coverage of laboratory and clinical aspects, diagnosis, clinical management, routine laboratory practice, transfusion serology, haemostasis and pharmacology
- features state-of-the-art reviews of both basic and clinical research

FREE SAMPLE ISSUE

If you would like to judge for yourself how this journal might meet your requirements, write today for a free sample issue. We will send you, without obligation from you, a complimentary copy of **Blood Reviews**. You will then be able to confirm for yourself the usefulness and the value of this important new journal.

The journal's distinguished editorial board, led by Dr I Chanarin and Professor David W Golde, bring together contributors who will provide worldwide coverage of all sub-specialities of haematology.

EDITORS-IN-CHIEF

**I Chanarin, Clinical Research Centre,
Northwick Park Hospital, Harrow,
Middlesex, UK.**

**David W Golde, Chief, Division of
Hematology-Oncology, Department of
Medicine UCLA, Los Angeles, California, USA.**

EDITORIAL BOARD

Jacques Caen (Paris, France)
Peter Castaldi (Sydney, Australia)
Marcella Contreras (London, UK)
Robert Peter Gale (Los Angeles, USA)
Victor Hoffbrand (London, UK)
Wendell F Rosse (North Carolina, USA)

CONTENTS OF THE FIRST ISSUE

Editorial Note Thrombosis

Hypercoagulability and Ischaemic Heart Disease
T. W. Meade

Aspirin and Other Antiplatelet Drugs in the Prophylaxis of Thrombosis
J. Webster, A. S. Douglas

The Lupus Anticoagulant and its Role in Thrombosis
G. Tobelen, R. Cariou, A. Cernez

Haematological Neoplasia

High Risk Lymphoblastic Leukemia in Children: Prognostic Factors and Management

C.-H. Pui, W. M. Crist

Immunologic Classification of Lymphoma and Lymphoid Leukemia
K. A. Foote, R. P. Gale

The Myelodysplastic Syndromes
R. L. Verwiltghen, M. A. Boogaerts

Pharmacology

The Prophylaxis and Treatment of Malaria
P. A. Winstanley

Mechanisms and Management of Chemotherapy-induced Nausea and Vomiting
S. G. Allan

State of the Art

B19 Virus—a Pathogenic Human Parvovirus
J. R. Pattison

Subscription Details

Four issues of the journal will be published each year. Subscription for the year is £40.00 (UK), \$90.00 (USA) and £43.00 elsewhere. Special rates are available for trainees in haematology of £25.00, \$50.00 and £28.00 respectively.

Send your subscription or request for a sample copy to:

Blood Reviews, Churchill Livingstone, Dept BRBD, Robert Stevenson House,
1-3 Baxter's Place, Edinburgh EH1 3AF, UK.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to *BLOOD*. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: *BLOOD* will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the *BLOOD* Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared

in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in *BLOOD* represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a \$50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to: John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to *BLOOD* and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of *BLOOD* will assume that the authors of research papers published in *BLOOD* are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and two complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least ⅛ inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

PUZZLED ABOUT THOSE EXTRA REACTIONS? — The Answer . . . **MONOCLONALS**

New from Pel-Freez for Clinical and Basic Research, we have a large collection of Monoclonals (in excess of 200).

HUMAN LEUKOCYTES

B cells, T cells, (also activation markers), Natural killer cells, Monocytes, Granulocytes, Platelets (Gp Ib, Gp IIb-IIIa)

IMMUNOGLOBULINS

IgA, IgD, IgE, IgG subclasses, IgM, Lambda and Kappa chains

HLA MOLECULES

Class I, Class II, B₂-Microglobulin

COAGULATION FACTORS

Factor VIII, Fibrinogen, Fibronectin, Thrombospondin, Tissue Plasminogen Activator

BLOOD GROUPS

DIFFERENTIATION MARKERS ON HUMAN TISSUE

Keratin, Desmin, Villin, Vimentin, Neurofilament

PITUITARY HORMONES

HCG, FSH, LH, TSH, Prolactin, Thyroglobulin, Leukemia cell markers

TUMOR MARKERS

Alpha Foeto Protein, Carcinoembryonic Antigen

VIRAL ANTIGENS

STEROIDS AND OTHER HAPTENS

AND MORE

These monoclonals can be supplied as ascites fluid, or in fluoresceinated, biotinated or unconjugated forms. Second step reagents are available for ELISA assays, immunocytochemistry and immunofluorescence.

For research use only

Coagulation Factor Deficient Human Plasma

- Substrate Quality
- Stable
- Fresh Frozen
- Mono-Specific

COAGULATION DEFICIENCIES AVAILABLE:

Factor I (Afibrinogenemia)	Factor IX	VonWillebrand Trait
Factor II	Factor X	(Mild and Severe)
Factor V	Factor XI	Prekallikrein
Factor VII	Factor XII	Kininogen (HMW)
Factor VIII	Factor XIII	Passovoy Trait
Factor VIII Inhibitor		Protein C

HEMATOLOGY PRODUCTS AVAILABLE:

Pooled Normal Plasma
Assayed Normal Plasma
Platelet Free Plasma

Aged Serum
Adsorbed Plasma
Coumadinized Plasma

- Plasmas are fresh frozen, citrated plasmas drawn from carefully screened HUMAN donors with congenital coagulation factor deficiencies.
- Shipments are packed in dry ice and usually delivered within 24 hours.
- Special arrangements are made to ship plasma in required volumes in vials (0.5 to 5.0 ml), in bags or on standing orders.

GAMMAGARD®

Immune Globulin Intravenous (Human)

Efficacy: a product of
high titer count and
full antibody activity.

Immunoglobulin G deficiency: Bothersome at best, often deadly. Without fully functioning defenses, a patient is prey to a legion of pathogens: *Pseudomonas aeruginosa*, Group B *Streptococcus*, *Streptococcus pneumoniae*, and *Hemophilus influenzae*, to name just a few of the most common—and virulent.

Studies in mice have shown that a broad spectrum of problematic pathogens are countered by the high titers of antibody in GAMMAGARD® IGIV. Peak levels of IgG are reached as soon as an infusion is complete. So GAMMAGARD® IGIV offers immunocompromised patients the immediate protection they need.

Native immunoglobulin G antibody activities are retained, as well as the normal distribution of IgG subclasses. Our state-of-the-art ion exchange adsorption technology assures that GAMMAGARD® IGIV meets these important tests for efficacy.

In addition to titer counts and animal protection capability, to be safe an IGIV must also have a high degree of purity. For example, IGIV preparations with a significant amount of IgA have caused life-threatening anaphylactic reactions. The IgA content in GAMMAGARD® IGIV is very low—not more than 10 micrograms/ml. Result: today GAMMAGARD® IGIV is the only IGIV product not contraindicated in selective IgA deficiency. GAMMAGARD® IGIV should still be given with caution to IgA-deficient patients.

When your immunocompromised patients require protection, think of GAMMAGARD® IGIV—the IGIV with remarkably high titers for an impressive variety of pathogens, very low levels of IgA, and high levels of purified IgG monomer—in short, the IGIV with the characteristics your patients must have.

DIRECTION INSERT

Immune Globulin Intravenous (Human) GAMMAGARD®

DESCRIPTION

Immune Globulin Intravenous (Human), GAMMAGARD® is a sterile, dried, highly purified preparation of immunoglobulin which is derived from the cold ethanol fractionation process and is further purified using ultrafiltration and ion exchange adsorption. When reconstituted with the appropriate volume of diluent, this preparation contains approximately 50 mg of protein per mL, of which at least 90% is gamma globulin. The reconstituted product contains approximately 1% sodium chloride, not more than 20 mg/mL glucose, not more than 0.2 g/dL PEG, and 0.3M glycine as a stabilizing agent. It has a pH of 6.8 ± 0.4 .

The manufacturing process for Immune Globulin Intravenous (Human), GAMMAGARD, isolates gamma globulin without additional chemical or enzymatic modification and the Fc portion is maintained intact. Immune Globulin Intravenous (Human), GAMMAGARD contains all the immunoglobulin G antibody activities which are present in the donor population. On the average, the distribution of IgG subclasses present in this product is the same as is present in normal plasma.¹ Immune Globulin Intravenous (Human), GAMMAGARD contains only trace amounts of IgM and IgA.

Immune Globulin Intravenous (Human), GAMMAGARD contains no preservative.

This product has been prepared from large pools of human plasma which was taken only from plasma units found to have normal levels of alanine aminotransferase (ALT). Each unit of plasma used in the manufacture of this product has been found to be nonreactive for HBsAg and HTLV-III antibody by FDA approved tests.

CLINICAL PHARMACOLOGY

Immune Globulin Intravenous (Human), GAMMAGARD contains a broad spectrum of IgG antibodies against bacterial and viral agents that are capable of opsonization and neutralization of microbes and toxins.

Peak levels of IgG are reached immediately after infusion of Immune Globulin Intravenous (Human), GAMMAGARD. It has been shown that IgG is distributed relatively rapidly between plasma and extravascular fluid until approximately half of the total body pool is partitioned in the extravascular space. A rapid initial drop in serum levels is, therefore, to be expected.²

As a class, IgG survives longer *in vivo* than other serum proteins.^{2,3} Studies show that the half-life of Immune Globulin Intravenous (Human), GAMMAGARD is approximately 24 days. These findings are consistent with reports of a 21 to 25 day half-life for IgG.^{2,3,4} The half-life of IgG can vary considerably from person to person, however. In particular, high concentrations of IgG and hypermetabolism associated with fever and infection have been seen to coincide with a shortened half-life of IgG.^{2,3,4,5}

INDICATIONS AND USAGE

Antibody Deficiency

Immune Globulin Intravenous (Human), GAMMAGARD is efficacious in the treatment of primary immunodeficient states in which severe impairment of antibody forming capacity has

been shown, such as: congenital agammaglobulinemias, common variable immunodeficiency, Wiskott-Aldrich syndrome, and severe combined immunodeficiencies.^{4,5}

Immune Globulin Intravenous (Human), GAMMAGARD is especially useful when high levels or rapid elevation of circulating gamma globulins are desired or when intramuscular injections are contraindicated.

CONTRAINDICATIONS

None known.

WARNINGS

Immune Globulin Intravenous (Human), GAMMAGARD should only be administered intravenously. Other routes of administration have not been evaluated.

Immune Globulin Intravenous (Human), GAMMAGARD contains very low quantities of IgA (not more than $10 \mu\text{g/mL}$) and although no instances of anaphylaxis associated with the use of this product have been observed during the clinical trials, such reactions have been observed with other immunoglobulin products.^{5,6} Immune Globulin Intravenous (Human), GAMMAGARD should be given with caution to patients with antibodies to IgA or selective IgA deficiencies.

PRECAUTIONS

Drug Interaction

Admixtures of Immune Globulin Intravenous (Human), GAMMAGARD with other drugs have not been evaluated. It is recommended that Immune Globulin Intravenous (Human), GAMMAGARD be administered separately from other drugs or medication which the patient may be receiving.

Pregnancy Category C

Animal reproduction studies have not been conducted with Immune Globulin Intravenous (Human), GAMMAGARD. It is also not known whether Immune Globulin Intravenous (Human), GAMMAGARD can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Immune Globulin Intravenous (Human), GAMMAGARD should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

The incidence of untoward reactions to Immune Globulin Intravenous (Human), GAMMAGARD is low, although various minor reactions, such as headache, fatigue, chills, backache, lightheadedness, fever and nausea may occasionally occur. The incidence of these reactions during the clinical trials was less than 6%. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Immediate anaphylactic and hypersensitivity reactions due to previous sensitization, although they have not been observed during the clinical trials, are a possibility. Epinephrine should be available for treatment of any acute anaphylactoid reaction. (See WARNINGS.)

DOSAGE AND ADMINISTRATION

Antibody Deficiency

For patients with primary immunodeficiencies, monthly doses of at least 100 mg/kg are recommended. Initially, patients may receive 200-400 mg/kg. As there are significant differences in the half-life of IgG among patients with primary immunodeficiencies, the frequency and amount of immunoglobulin therapy may vary from patient to patient. The proper amount can be determined by

monitoring clinical response and/or the serum IgG levels before each dose, to insure that they do not drop below 500 mg/dL.

Rate of Administration

It is recommended that initially a rate of 0.5 mL/kg per Hr be used. If infusion at this rate causes the patient no distress, the administration rate may be gradually increased but should not exceed 4 mL/kg per Hr.

A rate of administration which is too rapid may cause flushing and changes in pulse rate and blood pressure. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Administration

Immune Globulin Intravenous (Human), GAMMAGARD should be administered as soon after reconstitution as possible. Administration should not begin more than 2 hours after reconstitution.

The reconstituted material should be at room temperature during administration.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Follow directions for use which accompany the administration set. If a Hyland set is not used, make sure the administration set contains an adequate filter.

How Supplied

Immune Globulin Intravenous (Human), GAMMAGARD is supplied in either 2.5 g or 5.0 g single use vials. Each vial of Immune Globulin Intravenous (Human), GAMMAGARD is furnished with a suitable volume of Sterile Water for Injection, USP, a transfer device and an administration set which contains an integral airway and a 15 micron filter.

Storage

Immune Globulin Intravenous (Human), GAMMAGARD should be stored under ordinary refrigeration, (2 to 8 °C, 36 to 46 °F). Freezing should be avoided to prevent the diluent bottle from breaking.

HEMOSTASIS and THROMBOSIS:

Basic Principles and Clinical Practice, 2nd Edition

Edited by Robert W. Colman, M.D.,
Jack Hirsh, M.D., Victor J. Marder, M.D.,
and Edwin W. Salzman, M.D.
115 Contributors.

bringing you coverage unmatched in breadth and depth

Now you can have at your command a total overview of hemostasis and thrombosis . . . wide-ranging in scope, practical in focus, in a convenient one-volume source. With this comprehensive, multi-authored book at hand, you can consult with other specialists at any time on important clinical matters.

in a new edition—to bring you thoroughly up to date

More than half of the original 81 chapters have been extensively revised and updated. Another quarter of the chapters have been rewritten by new contributors. There are more detailed discussions of clinical problems, and improved groupings of chapters.

17 entirely new chapters on entirely new topics

- genetics of blood coagulation factors ■ the protein C system
- adhesive proteins ■ Factor V
- pathophysiology of fibrinolysis ■ renal disease
- management of thrombocytopenia ■ extracorporeal circulation
- platelet-vessel wall interactions
- treatment of hemorrhagic and thrombotic complications in pediatrics, obstetrics, and infectious disease
- and more!

No-Risk Guarantee

You can examine this new edition of **Hemostasis and Thrombosis** for 30 days with no obligation. Just fill out and return the convenient coupon below. If you're not completely satisfied just return the book within 30 days and owe nothing. That's our no-risk guarantee.

put these special features to work for you

- full coverage of both hemostasis and thrombosis
- detailed treatment of vessel wall physiology
- integration of basic science information with practical clinical management specifics
- thorough discussions of virtually all medical and surgical therapies
- nearly 15,000 references
- extensive cross referencing
- all brought to you by recognized experts in the field.

look at what reviewers said about the first edition

***JAMA:** "... a volume made to cover 'everything' . . . contains essentially a *Who's Who* of mainly American experts . . . superb electron micrographs . . . **the** reference work on this topic . . ."

The New England Journal of Medicine: "... incisive . . . a balanced view of the practical application of a wide range of available medical and surgical therapies. The references at the end of each chapter are extensive . . . destined to be a classic . . ."

Mayo Clinic Proceedings: "... encyclopedic . . . excellent . . . easily readable . . . a most comprehensive, in-depth, and up-to-date reference work . . ."

About 1,530 Pages. 400 Illustrations. 202 Tables.
Available April 1987. \$149.50.

1987 Helena Hemostasis Advanced Wet Workshops

What Is It?

A series of comprehensive, advanced, one day Hemostasis Wet Workshops presented by Helena Laboratories. The session will include lectures on the PFI (Proenzyme Functional Inhibitor) Index, platelet aggregation and chromogenic substrates as well as hands-on training with AT-III. Workshop participants will perform the COATEST® Antithrombin Chromogenic Assay using Microtiter plates. This procedure is just one demonstration of cost reduction with advanced technology for your lab.

Why Should I Attend?

These key topics will be covered.

Chromogenic Substrates —

We will discuss the clinical applications of chromogenic substrates.

As chromogenic substrate research progresses new products become available for the clinical lab. These new substrates allow the coagulation laboratory to perform sensitive, specific assays for various components of the hemostatic system.

AT-III Microplate Procedures —

Hands-on training with AT-III, levels can be measured easily with the COATEST Antithrombin Kit. The kit utilizes chromogenic substrate methodology to detect the conversion of pNA by thrombin spectrophotometrically. For greater efficiency, it can be automated on most centrifugal analyzers or run in microtiter plates.

NEW

PFI Index — A lecture and slide series on a new diagnostic tool for management of intensive care patients. The use of the Proenzyme Functional Inhibitor (PFI) Index allows the clinician to identify high-risk patients, obtain

prognostic information, and judge therapeutic effectiveness.

NEW

COA-SET Assays — KabiVitrum chromogenic substrates contribute greatly to the investigation of coagulation and fibrinolysis. Two new assays, COA-SET t-PA/t-PA Inhibitor and COA-SET Protein C will be discussed.

Platelet Aggregation — See the only aggregometer with a 4 color printer, making interpretation simple. Helena's Monitor IV PLUS Platelet Aggregation Recorder, features the ease and accuracy of automated 4 channel aggregation, and a 7 inch CRT for data entry display and preview.

NEW

Helena "Q.I.C" Bleeding Time Device — We'll introduce a new bleeding time procedure and discuss the diagnostic value of bleeding time testing for platelet defects and some vascular disorders.

When and Where?

1987 Advanced Hemostasis Spring Workshop Schedule

April	6	Raleigh, NC	May	4	Seattle, WA
	7	Miami, FL		5	Portland, OR
	8	Atlanta, GA		6	San Francisco, CA
	9	Memphis, TN		7	Los Angeles, CA
	10	New Orleans, LA		8	San Diego, CA
April	27	Denver, CO	June	1	Boston, MA
	28	Phoenix, AZ		2	Hartford, CT
	29	Dallas, TX		3	New York, NY
	30	San Antonio, TX		4	Philadelphia, PA
May	1	Houston, TX		5	Washington, DC
May	18	Minneapolis, MN			
	19	Chicago, IL			
	20	Detroit, MI			
	21	Cincinnati, OH			
	22	Pittsburgh, PA			

Guest Speaker — A representative from KabiVitrum in Sweden will be joining us again this year in our presentation of the Advanced Hemostasis Wet Workshops. This will be an excellent opportunity for you to meet and talk with one of the scientists who formulate and stand behind the innovative technology of chromogenic substrates.

How Do I Get More Information?

All laboratory professionals (managers, supervisors, technologists, pathologists, hematologists and coagulation researchers) are welcome. For more information call our Workshop Registrar toll free 800-231-5663. In Texas, 800-392-3126.

IMPROVING LIVES THROUGH RESEARCH

REVIEW**Protein Kinase C and the Activation of the Human Neutrophil NADPH-Oxidase**

By Alfred I. Tauber

THE NEUTROPHIL leads a short but dynamic life. Attuned to the vagaries of surveillance and destruction, it has developed a complex functional repertoire: Chemotaxis, adherence/aggregation, phagocytosis, degranulation, and oxidative burst require multi-component modes of response which, although highly integrated, may also be studied in dissected form.¹⁻⁶ The problem of signal transduction is a major focus of current study in cell biology, and the neutrophil has become a model of such inquiry, as attention to its various activities has discerned the outlines of its informational response pathways. Within this context, I wish to review the current understanding of the activation mechanism of the respiratory burst enzyme, nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase, as a paradigm of neutrophil secretory systems. This activity, defective in chronic granulomatous disease (CGD), is the principal defense against a wide variety of bacteria, and thus serves a crucial role in normal host defense.^{3,7} That a normal respiratory burst is dependent on appropriate receptor function, intact activating pathways, and an integral NADPH-oxidase (which in itself is multicomponent),⁷⁻¹¹ predicts multiple sites at which a biochemical lesion may arrest the complex cascade. With recent studies in broken cell systems, important insights into the sequence of activation steps required for normal neutrophil response have been made. By tracing exogenous agonist-induced stimulation of the NADPH-oxidase, the basic elements of the activation sequence are now discerned.

The human neutrophil has several well-defined receptors, including those for various components of C3,¹² immunoglobulin,¹³ the formyl-methionyl (FMLP) bacterial peptides,¹⁴ and leukotriene B₄.¹⁵ A recently described receptor is the ubiquitous protein kinase C (PK-C), a calcium, phospholipid-dependent kinase, activated by exogenous phorbol esters (eg, phorbol myristate acetate, PMA), and endogenously by diacylglycerol liberated by the action of phospholipase or phosphodiesterase.¹⁶ The evidence that receptor-ligand binding is critical in the activation of the metabolic burst is the correlation between ligand binding and biochemical expression. A receptor-binding linkage to NADPH-oxidase activation for PMA has been established.¹⁷⁻¹⁹ Patients with classically described CGD have not been reported to have abnormal receptor affinities as inferred by normal chemotactic and phagocytic responses^{3,8} or phorbol ester receptor binding,¹⁸ but certain patients have demonstrated selected responses to various stimuli and thus exhibit

a defect in the activation apparatus²⁰⁻²²; those with either congenital²¹ or acquired defects³ in PMA-induced oxidase activation are of particular interest. Thus, CGD, which includes all defects of the oxidative metabolic effector system, may be divided into two types: abnormal activating mechanisms and abnormalities of NADPH-oxidase.³

The activation of the human neutrophil by PMA leads to a spectrum of responses, including aggregation,²³ stimulation of the respiratory burst,^{17-19,24-26} depolarization of the plasma membrane,²⁷ enhanced phospholipid turnover,²⁸⁻³⁰ and degranulation of specific granules.³¹ The same constituent of the NADPH-oxidase found in the plasma membrane have been putatively reported in the specific granule membrane; upon PMA stimulation, a subset of these granules is translocated to the plasma membrane, the site of the active respiratory burst enzyme.^{32,33} Of the various stimulus-response-coupled functions defined for the normal neutrophil, I wish to focus on those biochemical phenomena related to the PMA receptor linked to the expression of NADPH-oxidase. In bypassing many associated complex metabolic activities, the PK-C system is a promising avenue for elucidating oxidase activation, at a site just proximal to the final expression of the respiratory burst enzyme. This PK-C dependent pathway is not the sole cascade for oxidase activation, however, since other soluble agonists and phagocytosed particles may bypass PK-C altogether.^{34,35} Although FMLP bypasses PK-C in elicited degranulation and oxidase activation, the chemotactic response is reduced by PK-C inhibition.³⁶⁻³⁸ Definition of parallel and cross-over points in the complex hierarchy of the activation process have yet to be discerned, and there is only general acknowledgment that more than one activation pathway may generate an active oxidase.

Recent studies have focused on the specificity of PMA for PK-C in eliciting a given biologic response. The synthetic diacylglycerol, 1-oleoyl-2-acetylglycerol (OAG), directly

stimulates PK-C and mimics PMA stimulation of oxidative burst activation.³⁹ Although both PMA⁴⁰ and OAG⁴¹ at submaximal concentrations exhibit synergism with the calcium ionophore, A23187, OAG has an apparent calcium dependence that PMA lacks.⁴² Another difference in response is the enhancement with calcium and arachidonate products observed with OAG stimulation, but not found with PMA.^{43,44} Dramatic functional differences have been observed in the HL-60 differentiation model, in which OAG totally fails to mimic the PMA-induced maturation of this tumor cell line⁴⁵; this apparent dissociation of PMA and PK-C has been confirmed with Bryostatin, another activator of PK-C that blocks PMA-induced HL-60 differentiation.⁴⁶ Interpretation of these data are difficult, however, because another target in addition to PK-C may be involved in this system, modulating the PK-C effect. Bryostatin, however, like OAG, does induce human neutrophil-specific granule release and oxidative burst similar to that of PMA stimulation.⁴⁰ Phosphorylation products were also similar when PMA and Bryostatin were compared in the same system (see below); thus, the ambiguity of the role of PK-C in HL-60 is not evident in the neutrophil.⁴⁷ Furthermore, the evidence for the role of PK-C in PMA-stimulated neutrophils rests most firmly on the reconstitution studies discussed (*sic infra*).

PHORBOL ESTER RECEPTOR

Correlation of phorbol ester's affinity characteristics to activation of the burst established that PMA and its analogue, phorbol 12,13 dibutyrate (PDBu), stimulated NADPH-oxidase through a specific receptor.^{17,18} Extension of studies with intact cells to the subcellular assessment of the oxidase demonstrated a similar dose-response activation profile.¹⁸ This evidence, linking ligand-receptor binding to initiation of the respiratory burst, is important support that NADPH-oxidase is indeed the principal enzymatic activity of the human neutrophil oxidative metabolic response. Characterization of the phorbol ester receptor showed that it was not susceptible to sulfhydryl reactive reagents, stilbene disulfonic acids, or neuraminidase, which explains the earlier findings of a lack of effect of these agents on the generation of O_2^- in PMA-stimulated cells, in contrast to cells stimulated with opsonized zymosan (OZ).^{48,49} The stimulus specificity demonstrated that the inhibition acted on distinct plasma membrane receptors and not on an oxidase exposed to the extracellular medium.

Studies of the PMA receptor suggested new approaches to defining the unknown pathways leading from receptor binding to activation of the oxidase, with the demonstration that the phorbol ester receptor is the calcium/phospholipid-dependent PK-C.¹⁶ In the neutrophil, PK-C exists as a cytosolic aporeceptor, with high phospholipid affinity for phosphatidylserine (PS).^{50,51} Phorbol esters mimic the elaboration of endogenous diacylglycerol required for an active PK-C complex^{16,52} (Fig 1). Diacylglycerol is generated as part of the complex phosphatidylinositol (PI) catabolism, which leads to the elaboration of inositol triphosphate, important for the release of intracellular calcium, a second messenger in diverse stimulus-coupled reactions.⁵³ Normally, diacylglycerol is almost absent from membranes but is

Fig 1. Schema of human neutrophil NADPH-oxidase activation as discussed in text. PDE, phosphodiesterase; DG, diacylglycerol; PLC, phospholipase C; PLA₂, phospholipase A₂; AA, arachidonic acid; PS, phosphatidylserine; Ins 1,4,5-PO₄, inositol triphosphate; O₂⁻, superoxide; ER, endoplasmic reticulum. The NADPH-oxidase is depicted as two adjoining square boxes.

transiently produced from PI in a signal-dependent manner by certain surface membrane receptors.^{54,55} The role of PI turnover and the accumulation of diacylglycerol has been intensively studied in several tissues, and a similar pathway has been described in neutrophils.⁵⁶⁻⁵⁹ PK-C activated in this manner shows multifunctional catalytic activity and appears to play roles in transmembrane control of protein phosphorylation in a variety of mammalian tissues. Phorbol esters are able to substitute for the diacylglycerol, and with PS and Ca²⁺, PMA directly activates the kinase and probably bypasses cyclic AMP- and cyclic GMP-modulated pathways.^{16,52,60} Thus, it is expected that pertussis toxin, which blocks the dissociation of regulatory G proteins and thereby inhibits their role in signal transduction,⁶¹ has no effect on PMA-stimulated cells, in contrast to neutrophils activated with FMLP.⁶² A caution is raised by the observation that a second undefined-G-protein-sensitive site may regulate exocytosis in PMA-activated cells,⁶³ suggesting the complexity of neutrophil response to this single agonist.

In the presence of optimal phospholipid and phorbol esters, the kinase is fully active at 10⁻⁷ mol/L of Ca²⁺, implying that the enzyme may be activated without a net increase in intracellular Ca²⁺ concentration when the appropriate receptors are stimulated. Indeed, PK-C has been reported as active at vanishingly low Ca²⁺ concentrations,^{64,65} and in PMA-stimulated neutrophils, a rise in intracellular calcium is not observed with the fluorescent probe Quin-2.⁶⁶⁻⁶⁸ This observation is based on the use of chemical indicator probes that may introduce an observational artifact.⁶⁹ Stimulation of PK-C only with agents (phorbol esters, teleocidin) other than diacylglycerol demonstrates this low Ca²⁺ dependence. Pontremoli and colleagues recently suggested⁷⁰ that PMA indeed mobilizes intracellular Ca²⁺ but, because of concomitant activation of a Ca²⁺ extrusion pump,⁷¹ a net change in intracellular Ca²⁺ is not observed. The role of Ca²⁺ mobilization in PMA-stimulated neutrophils has also been suggested by the inhibition of O₂⁻ generation observed with agents that inhibit intracellular Ca²⁺ mobilization⁷² or calmodulin,^{73,74} a Ca²⁺-dependent regulator of diverse function. These studies have been difficult to evaluate because of the nonspecificity of the inhibitors used^{67,75}; conclusions as to the role of ancillary Ca²⁺-dependent activities on PMA stimulation of the burst cannot as yet be made. Finally, Dougherty and Nidell showed that agents which alter cytosolic Ca²⁺ levels modulate binding of

phorbol diesters, suggesting a mechanism for the observed synergism between subthreshold activation of Ca^{2+} and PK-C pathways.⁷⁶ In this regard, the low level of recovery from broken cells of NADPH-oxidase with the reconstituted PK-C system (see below) may be due to omission of other metabolic tributaries contributing to PMA-initiated burst activation.

In the case of micromolar concentrations of calcium (a physiologic rise in Ca^{2+} induced by many agonists), the cytosolic form of PK-C and a Ca^{2+} requiring thiol proteinase, calpain, becomes associated with the neutrophil membrane.⁷⁷ The activation of calpain converts PK-C to a proteolytically modified Ca^{2+} /phospholipid-independent form, both in broken cell preparations and in intact cells stimulated with PMA.⁷⁸ Once the translocated PK-C has undergone proteolytic cleavage to a 65-kd species (from 85 kd), it is released to the cytosol in an active form, presumably accessible to other protein substrates. Whether oxidase activation requires membrane-bound PK-C^{51,70} remains to be demonstrated in the reconstituted system. The data thus far suggest that PK-C may be activated by two separate systems with different substrate targets, adding a second level of complexity to the control modulation of C-kinase-mediated functions. Furthermore, the stability of PK-C binding to the membrane appears to vary with the stimulus used.⁷⁹

Physiologic control mechanisms have been complicated further by the recent findings of Cox and co-workers, who demonstrated selective activation of the oxidase with synthetic diacylglycerols.⁸⁰ Of a series of synthetic *sn* 1,2-diacylglycerols, didecanoylglycerol (diC_{10}) induced lysosomal enzyme secretion but failed to stimulate the respiratory burst. Unlike other diacylglycerols that competed for all phorbol ester binding, diC_{10} competed for only 45% of the binding sites. The data showed a correlation of selective PK-C binding with a limited cellular response, and further suggested that a discrete pool of PK-C was responsible for activation of the NADPH-oxidase. These findings are of particular interest in regard to the recent identification of multiple, distinct forms of PK-C by cloning techniques.⁸¹⁻⁸³ The specificity and regulation of response has thus acquired a new molecular complexity.⁷⁸⁻⁸⁰ Determination of type-specific PK-C isoenzymes, with possibly differing activation characteristics and target proteins, promises to add a sophisticated dimension to the study of PK-C. Finally, an endogenous PK-C inhibitory factor (non-protease, non-phosphatase) associated with the specific granules has been partially characterized.⁸⁴ Its role, the substrates of the calpain system, the putative selective target pools of PK-C, and the subcellular localization of activated PK-C require extensive coordinated study to define physiologic control mechanisms of phorbol ester stimulation.

The rapid flux in lipids, mobilization of arachidonic acid (AA) by the activation of phospholipases, and the extensive turnover of membrane phospholipids during phagocytosis represent associated metabolic activities of the respiratory burst.^{3,53,57} Inhibitors of phospholipid turnover do inhibit chemotaxis and phagocytosis and may interfere in the activation sequence of the respiratory burst,^{2,3,5} but there is no direct evidence linking phospholipid turnover to activation of

the burst by PMA, in contrast to particulate stimulation.^{35,56} Phospholipid metabolism accompanies the activation process and likely contributes to membrane fluidity changes seen in the stimulated cell.^{3,85,86} Changes in total phospholipid composition are both time and stimulus dependent, the most dramatic change in PMA-stimulated cells being a net elaboration of PS noted during the first 3 minutes of stimulation.^{29,30} That the PMA aporeceptor is cytosolic and has a uniquely high affinity for PS, which appears most effective for the activated receptor,^{16,51,54} suggests that the PS elaborated has a functional role for PK-C activity, but the mechanism by which PS is elaborated in PMA-stimulated cells is not known.

OZ, which may activate the PI cascade described above,⁵⁶ stimulates O_2^- release by a mechanism distinct from that of PMA.³⁵ This has been amply demonstrated with neutrophils from patients with paroxysmal nocturnal hemoglobinuria³ and a congenital neutrophil dysfunctional case,²¹ in which response to OZ was intact, whereas PMA could not initiate a normal respiratory burst. Only recently have some of the biochemical parameters of the two agonists been defined (Fig 1). PMA differs from OZ stimulation in its susceptibility to a PK-C inhibitor (isoquinolinesulfonamide,⁸⁷) and the lack of PMA-initiated release of radiolabeled AA ($[^3\text{H}]\text{AA}$) from prelabeled cells.³⁵ The specific involvement of phospholipase A2 (PLA_2) in the release of AA in OZ-stimulated cells has been implicated, and the partial reduction of O_2^- formation observed with inhibitors of AA metabolism (BW755C and indomethacin) further supports a linkage between AA release and O_2^- generation in OZ-stimulated cells.³⁵ Finally, like O_2^- generation, $[^3\text{H}]\text{AA}$ release in OZ-stimulated cells is calcium dependent,³⁵ another difference from calcium-independent PMA activation.⁶⁶⁻⁶⁸ It is of interest that exogenous AA stimulates the respiratory burst in intact cells seemingly by the same PLA_2 -dependent pathway as with OZ, but in this case, inhibition of AA metabolism has no effect on O_2^- generation.⁸⁸ In toto, opsonized particle stimulation of the NADPH-oxidase differs from PMA in that the particulate stimulus is PLA_2 mediated, calcium dependent and independent of PK-C. These studies suggest that this physiologic stimulus, binding to plasma membrane receptors, induces an activation cascade biochemically distinct from that generated when PK-C is directly stimulated by phorbol esters. PMA, in bypassing these associated lipid metabolic activities, allows examination of the activation cascade at a point distal to them. This is a useful juncture at which to study the activation of the NADPH-oxidase directly.

*A role for Ca^{2+} in PMA-activated neutrophils has been implicated in preliminary studies, which show that when cells are depleted of intracellular Ca^{2+} , or when intracellular Ca^{2+} mobilization is blocked, O_2^- generation and depolarization are abolished in a Ca^{2+} -free buffer. The effective extracellular Ca^{2+} concentration that restores 50% activity is 100 $\mu\text{mol/L}$ for depolarization and 1 $\mu\text{mol/L}$ for O_2^- production, suggesting different requirements for these functions. Considering the Ca^{2+} requirement of PK-C, these findings are expected, and thus the apparent Ca^{2+} -independence of PMA stimulation is only relatively low as compared to other agonists.^{65a}

PK-C ACTIVATION OF NADPH-OXIDASE

The respiratory burst enzyme, NADPH-oxidase, is maximally stimulated by PMA⁴⁹; the electrons utilized to produce reactive oxygen species arise from the activation of the hexose monophosphate (HMP) shunt, which not only supplies NADPH (the reducing agent) but also stoichiometrically generates one proton for each electron required to reduce molecular oxygen to superoxide.⁸⁹ The protons are secreted largely by a sodium-proton antiporter, whose control of cellular pH appears to regulate cell activation in an as yet undefined manner.⁹⁰ In the initial studies of PK-C activation of the NADPH-oxidase, distribution of PDBu binding was measured.⁹¹ Almost 95% of the specific [³H]PDBu binding was found in the cytosolic fraction of unstimulated, nitrogen-cavitated neutrophils, with a specific binding activity of 8.6 pmol/mg protein. The K_d for [³H]PDBu binding to the cytosolic fraction reconstituted with PS determined by Scatchard analysis was 1.2 nmol/L ($n = 3$). This value is similar to that determined for the partially purified receptors from mouse brain cytosol.⁹² This affinity is considerably higher than that observed in intact cells (38 nm),¹⁸ presumably reflecting the reconstitution of the receptor in PS rather than the actual phospholipids of the neutrophil membranes.

No significant difference was found in the distribution of the binding activity between the subcellular fractions of control and PMA-stimulated neutrophils, in contrast to findings in other studies.^{19,51} Because phorbol ester treatment has been reported to induce changes in apparent PK-C distribution in neutrophils and some other systems^{51,70,77,93,94} under other lysis conditions, these discrepancies may reflect the extractability of the potentially redistributed receptors under certain fractionation conditions. Because different methods of cell breakage and assay have been used, this issue has not been resolved. It remains to be determined if the site of action of PK-C in activating the NADPH-oxidase is direct phosphorylation of the plasma membrane-bound NADPH-oxidase or modification of a cytosolic regulatory component which could then act on the oxidase.

Regardless of the transport of PK-C in intact cells, which appears to require membrane binding in physiologic stimulation,⁹⁵ *in vitro* manipulation, based on these binding studies of phorbol ester, has reconstituted a functional activation of the NADPH-oxidase. Previous studies showed that the membrane-bound NADPH-oxidase may be activated in a broken cell system by the addition of AA to a cytosolic factor.⁹⁶⁻⁹⁸ Those studies were extended by characterizing the pathway of oxidase activation through the PK-C system. PMA alone was unable to stimulate the oxidase in disrupted neutrophils when tested at concentrations corresponding to ~50-fold the K_d for the phorbol ester receptor; however, under specific conditions appropriate for PK-C activation, namely inclusion of PMA, PS, ATP, and a cytosolic factor, the NADPH-oxidase was activated.⁹¹

In these PK-C reconstitution studies, separation of the cytosol fraction and a light membrane fraction, the site of NADPH-oxidase in prefractionated PMA-stimulated neu-

trophils,³³ enabled definition of the basic requirements of the reconstituted oxidase system. Each component of a reconstituted PK-C system was required for NADPH-oxidase expression. The dependence of oxidase activation on particular phospholipids paralleled that for PK-C studies in other tissues.⁹² The Ca^{2+} dependence of the reaction could only be demonstrated with the addition of EGTA. Residual Ca^{2+} in the cytoplasm and leached membrane Ca^{2+} was presumably sufficient for reconstitution of activity. The dose-response curve for PMA revealed a half-maximally effective dose of 1.1 nmol/L, which was consistent with the high affinity of PMA for PK-C⁹⁹ and the measured amount of PK-C in the cytosol preparations. When purified PK-C obtained from mouse brain and its co-factors were substituted for cytosol, the NADPH-oxidase was similarly activated. Quantitatively, the levels of PK-C in the cytosol corresponded with the added purified enzyme.

As noted, activation of NADPH-oxidase has been achieved in broken cell preparations by adding AA,⁹⁶⁻⁹⁸ oleic acid,¹⁰⁰ or sodium dodecyl sulfate (SDS)¹⁰¹ to the membrane-bound oxidase. In these studies, an additional soluble factor was required, but it does not appear to be PK-C, as originally suggested. AA, oleate, or other oxygenated fatty acid derivatives activate PK-C directly,¹⁰²⁻¹⁰⁴ and AA inhibits specific [³H]PDBu binding to the cytosolic neutrophil phorbol ester receptor, with a K_i of 38 μ mol/L and an ID_{50} of 190 μ mol/L (P.M. Blumberg and A.I. Tauber, unpublished observations), values similar to those obtained using partially purified PK-C from mouse brain.¹⁰⁵ The mechanism for NADPH-oxidase activation by arachidonate in the *in vitro* setting does not correlate with these observations, however, and suggests that either another metabolic pathway is used or stimulation occurs by a nonenzymatic process. In both AA and SDS NADPH-oxidase broken-cell-stimulated systems, the PK-C inhibitor isoquinolinesulfonamide had no significant effect, supporting pathways of AA and SDS oxidase activation independent from that of PMA.¹⁰⁶

The initial characterization of the cytosolic factor(s) for arachidonate stimulation of the oxidase has shown that although they are Mg^{2+} -dependent, phospholipid, ATP, and GTP are not involved.^{106,107} Curnutte and colleagues showed that their putative soluble factor had no PK-C activity, and in a patient missing this factor, the level of neutrophil PK-C was normal.¹⁰⁸ As in their previous report,¹⁰⁹ the patient did not respond to PMA, suggesting that the cytosolic factor was either independent of PK-C or played its role distal to PK-C activation. It is of interest that the multifunctional kinase activator, calmodulin, has been implicated in oxidase activation by AA¹¹⁰ and other soluble agonists,¹¹¹⁻¹¹³ but only one preliminary report has used a calmodulin inhibitor in the broken cell AA-stimulated system and shown a possible linkage.¹¹⁴ The role of calmodulin in neutrophil activation, and in particular, its relation to PK-C, is as yet unclear. Finally, the correlation between intact cell activation with AA and that observed with broken cells is poor in that the former is Ca^{2+} dependent and releases prelabeled [³H]AA whereas the latter system is Ca^{2+} independent and does not depend on a putative PLA₂ function for oxidase expression.⁸⁸

The data suggest distinct mechanisms by which the NADPH-oxidase is stimulated in intact cells and membrane fractions by AA.

Although the precise stimulatory pathway or the physico-chemical correlates of AA or SDS activation have not been discerned, the evidence is compelling that AA and SDS activate the NADPH-oxidase by a PK-C-independent mechanism. Because the PK-C-stimulated oxidase is only 15% as active as that obtained with AA or SDS activation (which are comparable),¹⁰⁶ it may represent either a less efficiently reconstituted system or an ancillary arm of AA or SDS activation. The mechanism of the PK-C-independent activation may suggest the properties required for oxidase expression. One model for oxidase expression is based on the movement and juxtaposition of oxidase components for electron transfer from NADPH to oxygen. Badwey and colleagues, in studies with intact cells, first suggested that AA may activate the respiratory burst by effecting membrane fluidity changes in the locale of the NADPH-oxidase,¹¹⁵ and Bromberg and Pick postulate that AA and SDS activate the oxidase by their detergent properties.¹⁰¹ The physiological correlation to the PMA/PK-C system is that phosphorylation of a component (or possibly an intermediary mediator) affects the stereo-relationship of oxidase components, resulting in effective juxtaposition for electron transfer.

PUTATIVE PK-C PHOSPHORYLATED PRODUCTS

The roles of neutrophil protein phosphorylation have been examined with regard to the activation of the respiratory burst, since increased kinase or phosphatase activity with concomitant phosphorylation or dephosphorylation of target proteins represents an important regulatory mechanism in a variety of mammalian cells. Earlier work has identified human neutrophil protein kinases and phosphatases, but their functional roles have not been definitively determined.¹¹⁶ This issue may now be reexamined with our new understanding of PK-C and with the use of well-defined subcellular fractions.

Recognition of relevant phosphate acceptor proteins is one of the major problems for defining the effects of protein kinases in general. When tested in cell-free systems, PK-C shows broad substrate specificity and phosphorylates many endogenous unidentified proteins in most tissues. Apparently, protein kinases C and A often use the same phosphate acceptor proteins.^{117,118} For example, both enzymes phosphorylate, to various extents, seryl and threonyl residues in many membrane-bound proteins. A preliminary analysis suggests that the sites of phosphorylation overlap to some extent, but several seryl and threonyl residues are phosphorylated specifically by PK-C. The relative reaction velocities differ among the substrate proteins used, and the seryl and threonyl residues vary in amount and location. When H1 histone is used as a model substrate, the biochemical specificity is well illustrated: protein kinase A greatly favors a seryl residue (serine-38) located near the N-terminus, whereas protein kinase C rapidly phosphorylates both seryl and threonyl residues located near the C-terminus.^{119,120} Isolation of PK-C from bovine¹²¹ and rabbit¹²² neutrophils was

recently reported. Activity and biochemical characterization appear to correspond closely to PK-C preparations from other tissues.¹⁶

The role of PK-C-mediated protein phosphorylation in the activation of NADPH-oxidase has been studied by several groups using different neutrophil sources and techniques for demonstrating phosphorylated products. Not surprisingly, the reported findings show discrepancies and inconsistencies, making a coherent statement as to the identification of PK-C dependent phosphorylations impossible. The two most important lines of evidence that the identification of such products is crucial come from (a) the previously mentioned studies indicating that a functional oxidase arises from the reconstituted PK-C system, and (b) the recent demonstrations that both autosomal recessive¹²³ and X-linked¹²⁴ CGD patients lack phosphorylation of proteins of 44 to 48 kd. Although X-linked CGD has been associated with a defective or absent low potential b cytochrome,^{10,125} the molecular basis of autosomal CGD has not previously been established. The discrepancy that Segal does not find a phosphorylation defect in his X-linked CGD patients, but finds such a defect only in autosomal cases,¹²³ remains to be resolved. Heterogeneity of CGD defects is well known^{3,33} and the recent cloning by Orkin and co-workers of a missing protein found in some X-linked CGD cases that has no homology with known cytochromes has even raised uncertainty as to the significance of the b cytochrome as a molecular marker of the X-linked disease.¹²⁶ The tantalizing reports of Segal¹²³ and Babior¹²⁴ need to be pursued, with identification, isolation, and characterization of the putative crucial phosphorylated proteins in normal cells.

Previously, a major difficulty appears to have arisen from the use of insufficiently defined systems for analysis.^{124,127} Because the NADPH-oxidase has been localized to the plasma membrane, it seems appropriate to study the phosphorylated products at this site, or better, in a partially purified oxidase preparation. Recently, Rossi and colleagues examined such a preparation from pig neutrophils; the NADPH-oxidase was solubilized and filtered over Ultragel. Rossi found several phosphorylated products, but a 31.5-kd protein was prominently phosphorylated by an apparent PK-C-mediated mechanism,¹²⁸ and he suggested that this product was a component of the previously characterized oxidase.¹²⁹ Sha'afi's group also identified a 31-kd phosphorylated product in PMA-stimulated rabbit neutrophil plasma membranes, yielding a small, but consistent image. This protein was the only one identified as exclusively found in plasma membranes but was not further characterized.¹³⁰ Another protein of 50 kd appears to be a major PK-C substrate; while it correlates closely with degranulation, its relation to the activation cascade has not been further elucidated.^{130,131} An early study of a reconstituted PK-C system incubated with disrupted neutrophils identified major phosphorylated membrane-bound products of 38 and 34 kd, but the relationship of these products to oxidase activation was not investigated.⁵⁰ Babior found a 22-kd protein exclusively in the particulate fraction of disrupted human neutrophils prestimulated with PMA.¹³² Romeo's group, using

enucleated, granule-free cytoplasm ghosts (cytosol-free) found six PK-C-mediated phosphorylated products, but did not attempt to relate these targeted proteins to oxidase function.¹³³ One of these products is a 47-kd protein. An earlier Romeo study of human neutrophils could not distinguish PK-C specifically labeled proteins primarily because of the undifferentiated system of analysis used.¹³⁴ Okamura and colleagues attempted to relate this 46-kd species (probably two proteins with distinct pIs of 7.4 and 6.4) to NADPH-oxidase activation.¹³⁵ This study, using guinea pig neutrophils, found the 46-kd proteins in a membrane precipitate, but again their relation to oxidase activation was not established. We find the claim interesting only in light of the corresponding size of the missing proteins reported in the CGD studies of Segal and Babior.^{123,124}

Other activators of PK-C have also been used to examine phosphorylation products of the human neutrophil. Using preloaded cells stimulated with OAG, and two-dimensional gel electrophoresis, Fujita and co-workers observed four prominent images, but did not attempt to link any of these to oxidase activation.¹³⁹ Berkow and Kraft recently compared PMA- and Bryostatin-stimulated neutrophils and found unique products of 93, 88, 66 and 45 kd in a one-dimensional system⁴⁷; Bryostatin induced phosphorylation of an additional protein of 70 kd. The similar pattern supports the same mechanism of cell activation by these stimuli.

These previous studies alerted workers to the problems of (a) using a prelabeled intact cell system that cannot distin-

guish those products crucial to oxidase expression from other stimulated activities; (b) the high number of competing, non-PK-C kinase activities, which are not controlled in intact cell systems; (c) the complexity of phosphorylation patterns if purified membranes from the same animal or human source are not used; and (d) the necessity of relating phosphorylated products directly to oxidase expression. New approaches to defining the mechanism of PMA/PK-C-mediated activation of NADPH-oxidase must use a minimal system to reduce the number of phosphorylated products for study. Purified PK-C incubated with purified membranes containing the oxidase offers the opportunity to examine this process with minimal competing reactions and the fewest selected phosphorylation targets. Corresponding kinetics, inhibitor studies and PK-C specificity should identify those products(s) crucial for NADPH-oxidase activation by the PK-C system, which can then be confirmed with studies of CGD cells and corresponding studies with intact cells. Once identified, characterized, and isolated, the NADPH-oxidase activation system may be dissected and then reconstituted. Although this is an ambitious undertaking, the reward for tracing this receptor-ligand-coupled reaction is understanding of a major mechanism of signal transduction.

ACKNOWLEDGMENT

I gratefully appreciate the useful comments of Dr Peter M. Blumberg and acknowledge the expert secretarial assistance of A.M. Happpie.

Diversity of the Effect of Recombinant Tumor Necrosis Factors α and β on Human Myelogenous Leukemia Cell Lines

By Miloslav Beran, Borje S. Andersson, Peter Kelleher, Kathleen Whalen, Kenneth McCredie, and Jordan Gutterman

In vitro characteristics of response to recombinant tumor necrosis factors α (rTNF- α) and β (rTNF- β) were studied in six human myelogenous leukemia cell lines. Heterogeneity of the response to rTNF was observed, and one line (K562) was resistant. No enhancement of cell growth was noted in any cell line. The dose-response curves for rTNF- α were characteristically sigmoid, the maximum inhibitory effect occurring between 25 and 200 ng/mL. Nonresponsiveness within this range indicated resistance that could not be overcome, even with very high doses of rTNF- α . A similar response of sensitive and resistant lines occurred after exposure to rTNF- β . The clonogenic cells were more sensitive than the overall population to the action of

rTNF- α , and prolonged exposure was necessary for manifestation of the effect. Concomitant exposure to recombinant interferon- α (rIFN- α) increased the response of two cell lines to rTNF- α , but no clear synergistic action could be demonstrated. The addition of rIFN- γ was without effect. Variations in the rTNF- α -induced proliferative response could not be explained by differences in the number of binding sites per cell or their affinity for rTNF- α . That the clonogenic cells showed a higher sensitivity than the whole population might indicate a preferential effect on more primitive, actively proliferating cells with high growth potential.

TUMOR NECROSIS FACTOR (TNF)^{1,2} and lymphotoxin³⁻⁵ were originally described as products of stimulated monocytes-macrophages and lymphocytes, respectively. These lymphokines are characterized in vitro by their lytic or antiproliferative effect on certain transformed cell lines.⁶⁻¹² In vivo they induce hemorrhagic necrosis of both autologous and heterotransplanted tumors.^{1,8,13,14} In numerous studies, there have been reports on variations of the in vitro activity of TNF in different animal and human cell lines,¹⁻¹⁵ but no myelogenous leukemia lines have been studied so far. Little is known about the modes of action of TNF.^{2,15,16} Only recently, because of the availability of pure molecules,¹⁷⁻²⁰ can the mechanism of action be properly studied. It was recently reported that recombinant TNF (rTNF) does inhibit growth of certain tumor cell lines while being indifferent or stimulatory to others,¹² and a similar observation was made with purified lymphotoxin.⁷

The activity of these lymphokines in normal and malignant human hematopoiesis is largely unknown at present. TNF is produced by both normal and malignant monocytes-macrophages²⁰⁻²² and natural killer (NK) cells.²³ Thus, its action on human leukemic cells is of particular interest since we have observed inhibition of leukemic clonogenic growth by human macrophages²⁴ and NK cells.²⁵ Myelogenous leukemia is a heterogeneous disease, both morphologically and cytogenetically.²⁶ We were interested in whether this heterogeneity is reflected in the in vitro response to TNFs. Of particular interest to us was the role of TNF receptors and the relation of the TNF response to the phenotypic properties of the cell lines. We therefore investigated the following aspects of cell-TNF interactions: (a) the dose response of leukemic clonogenic cells to rTNF- α ^{12,20} and lymphotoxin or TNF- β (rTNF- β)^{12,19}; (b) the action of rTNF- α on clonogenic cells as compared with the whole leukemic cell population; and (c) the receptor density and binding affinity to cellular receptors of radiolabeled rTNF- α .

Interferons have had antiproliferative activity in some leukemic cell lines studied (M. Beran, unpublished observations), and synergism between interferons and TNFs has been reported in some cell systems.^{7,9,10} Therefore, we also investigated a possible enhancement of the TNF response in TNF-sensitive and TNF-resistant leukemic cell lines by rIFN- α and IFN- γ . Because clonogenic cells are responsible

for the continuous growth of a tumor, we primarily chose to study the effect of rTNFs on these cells rather than the whole population of tumor cells.

MATERIALS AND METHODS

Lymphokines. Recombinant technology-produced interferon- γ (rIFN- γ , specific activity, 4×10^7 U/mg), rTNF- α (specific activity, 3.7×10^7 U/mg), and lymphotoxin or rTNF- β (specific activity, 2.5×10^7 U/mg) were all gifts from Genentech (San Francisco). Recombinant rIFN- α , a gift from Hoffman LaRoche (Nutley, NJ) had a specific activity of 2.0×10^8 U/mg. Stock preparations were stored at 4°C in sterile vials. Dilutions were made immediately prior to use in sterile phosphate-buffered saline (PBS) supplemented with 5% fetal calf serum (FCS). The amount of rTNF- α and rTNF- β is given in nanograms rather than in units to avoid controversy related to differences in the sensitivity of various assay TNF systems.

Leukemic cell lines. Six different cell lines²⁷⁻³⁰ derived from patients with acute myelogenous leukemia (AML) or blastic crisis of chronic myelogenous leukemia (CML-BC) were used in the present study (Table 1). One additional subline of KBM-3, rendered resistant to Adriamycin (KBM-3/Adria), was also used.

All leukemic cells were maintained as suspension cultures in Iscove's modification of Dulbecco's medium (IMDM) (Irvine Scientific, Santa Ana, CA) supplemented with 10% to 15% FCS. They were used for experiments when in exponential growth phase.

Clonogenic assay. All leukemic cell lines that were used produced clones in semisolid media, without an external source of specific growth factors. The cloning system used was a standard, single-layer agar media culture system. Cells were suspended in IMDM supplemented with 15% FCS, L-glutamine, penicillin, streptomycin, and 0.3% agar (Bacto-Agar, GIBCO, Grand Island, NY). One milliliter of media, containing 5 to 10×10^3 cells, was added to

35-mm tissue culture Petri dishes (Nunc, Denmark) and allowed to solidify. Cultures were then incubated at 37 °C in a fully humidified atmosphere of 5% CO₂ in air. After 7 days, clones containing more than eight cells were scored. All cultures were made in triplicate for each experiment.

Normal human bone marrow granulocyte-macrophage progenitors (GM-CFCs). Bone marrow was obtained from six normal volunteers and light-density fraction, devoid of erythrocytes and granulocytes obtained using one-step Hypaque-Ficoll (density 1.080 g/mL). In accordance with institutional guidelines, all patients and volunteers were advised of bone marrow aspiration procedures and attendant risks and gave informed consent. After removal of adherent cells by incubation in plastic bottles for 2 hours with 20% FCS, the nonadherent cells were used for comparative study on the effect of rTNF- α . Cells (1×10^5 mL) were suspended in IMDM supplemented with 20% FCS, 0.3% agar, and increasing concentrations of rTNF- α (1×10^{-2} to 1×10^3 ng/mL). One milliliter was plated in 35-mm Petri dish on the top of 1 mL of media supplemented with 20% FCS, 0.5% agar, and 10% (vol/vol) of human placenta-conditioned medium (HPCM) as the source of colony-stimulating factor.^{31,32} Triplicate cultures were set up for each experimental point and incubated at 37 °C, 5% CO₂ in air for 6 days. Thereafter, clones containing ≥ 50 cells were scored, surviving fractions were calculated, and data were plotted as dose-response curves. The maximal achievable inhibition of clonal growth and the lowest dose of rTNF- α producing maximal inhibition was determined.

Assay on the effect of lymphokines in agar-media cultures. Recombinant IFN- α or IFN- γ , rTNF- α , and rTNF- β or their combinations were added in increasing concentrations to cells in semisolid cultures. In this system, the cells were continuously exposed at relatively low density to particular lymphokines. After the clones produced by surviving clonogenic cells were scored, survival curves were constructed by comparing the numbers of clones in experimental cultures with those from control plates. Surviving fractions were calculated. The results, expressed as means $\pm$ SD of triplicate cultures, were plotted on a log/log plot as dose-response curves.

Effect of rTNF- α on clonogenic cells in suspension cultures of leukemic cells. Short-term cultures were carried out in IMDM supplemented with 15% FCS. Cells (5×10^4 to 3×10^5 /mL) were added along with rTNF- α and incubated at 37 °C, 5% CO₂ in air. After 1 hour to 4 days, the cells were pelleted at 150 g for 10 minutes, the supernatant was discharged, and the cells were washed twice in warm PBS to remove unbound lymphokines. Cells were counted in a counting chamber, and viability was determined by trypan blue exclusion test. A fraction of cells was plated for determination of the surviving clonogenic cells. All suspension cultures were done in duplicate. From each culture, clonogenic assays were performed in triplicate as described above.

Radioiodination of rTNF- α . Radioiodination of rTNF- α was performed by the iodogen method³³ as described by Aggarwal and colleagues.³⁴ In brief, 10 μ g of rTNF- α in 0.1 mol/L of phosphate buffer (pH 7.4) was added to 0.5 mCi Na¹²⁵I in a tube coated with 5 μ g iodogen for 10 minutes at 4 °C. The reaction was stopped by

removing soluble material from the tube, and labeled rTNF- α was separated from free iodine by filtration on Sephadex G-10 equilibrated with 0.1 mol/L of phosphate buffer containing 0.1% gelatin and 0.05% Tween 20. ¹²⁵I-labeled TNF had a specific activity of ~ 630 Ci/mmol and gave a single band of 17,000 daltons by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). ¹²⁵I-labeled TNF retained 80% to 90% of its biological activity as assayed by the lysis of actinomycin D-treated mouse L929 cells.³⁵

TNF binding assays. Binding of ¹²⁵I-labeled TNF was performed as described for ¹²⁵I-labeled rIFN- α .³⁶ Cells were harvested by centrifugation at $1 \times 10^3 \times g$ for 10 minutes, resuspended in medium, and again pelleted. The cell pellet was resuspended in RPMI 1640, containing 0.1% bovine serum albumin (BSA), to a concentration of 1 to 2×10^7 cells/mL. Cell suspensions were incubated with either ¹²⁵I-labeled rTNF- α only for total binding or ¹²⁵I-labeled rTNF- α plus excess unlabeled ($\times 100$) rTNF- α to assay for nonspecific binding. After incubation for 2 hours at 24 °C 100- μ L aliquots were removed in triplicate and layered on cold (4 °C) sucrose double gradients (0.15 mol/L/0.30 mol/L). The tubes were centrifuged for 15 seconds at $13 \times 10^3 g$ in a Beckman tabletop microfuge (model no. 152) and immediately frozen in an alcohol-dry ice slurry. Bound (pelleted) and free (supernatant) ¹²⁵I-labeled rTNF- α were separated by cutting off the bottom part of the microtube. Specific binding was determined by calculating the difference between the total and the nonspecific binding. Calculated values of the number of binding sites per cell were obtained by Scatchard analysis of equilibrium binding data.³⁷ Student's *t* test was used to evaluate the significance of the results.

RESULTS

Effect of rTNF- α on clonogenic cells. An appreciable heterogeneity in the cloning ability of six different human myelogenous leukemia cell lines was observed in the continuous presence of rTNF- α in the culture medium (Fig 1, Table 2). The sensitivity range of GM-CFCs is presented for comparison (Table 2). The clonogenic cells of K562 line proved resistant to rTNF- α concentrations up to 5×10^3 ng/mL. In responsive cell lines, the dose-response curves on a log/log plot were sigmoid.

In all cell lines tested, a maximal inhibition of clonogenic growth was observed after the addition of ≤ 100 ng/mL rTNF- α . Further increase of the TNF concentration resulted in either a plateau or a decrease in the degree of inhibition. In sensitive cell lines, the major differences were observed after doses < 25 ng/mL (Fig 1). The KBM-3 cells proved exquisitely sensitive, significant inhibition being noted as reproducible at doses of 1×10^{-3} ng/mL; 10 ng/mL inhibited 99.8% of clonogenic cells. Stimulation of colony growth was not observed with any cell line in the dose range between 1×10^{-4} and 1×10^4 ng/mL.

Fig 1. Sensitivity of clonogenic cells from myelogenous leukemia cell lines to increasing doses of recombinant tumor necrosis factor- α (rTNF- α). Each point represents the mean of three experiments. (SD signs are omitted for simplicity.)

Comparison of the activity of rTNF- α and rTNF- β in leukemic clonogenic assay. In two cell lines selected for differences in their response to rTNF- α , the effect of rTNF- β was studied in the clonogenic assay. (Fig 2). Similar results were obtained with both lymphokines. In the sensitive (KBM-5) cell line, rTNF- β (lymphotoxin) proved less active on a wt/vol basis. In K-562 cells, the same resistance was shown to rTNF- α and rTNF- β .

Effect of rTNF- α on the growth of myelogenous leukemia cells in suspension cultures. In two rTNF- α -sensitive cell lines, we studied the effect of cell density on the inhibitory effect of rTNF- α . In HL-60 cells, the growth inhibition was more pronounced in cultures initiated at lower initial cell concentrations (Table 3). Evaluated by total cell numbers as endpoint, the phenomenon was found only in moderately sensitive HL-60 cells. In highly sensitive KBM-3 cells between 73% and 77% inhibition was found after 3 days of growth and the degree of growth inhibition was independent of the initial cell density. The cell viability assessed by trypan blue exclusion test was slightly but significantly ($P < .05$) lower in the presence of rTNF- α .

Effect of rTNF- α on clonogenic cells compared with the whole cell population in suspension cultures. HL-60 cells were grown in suspension culture at two different seeding cell densities, in the presence or absence of 500 ng/mL of rTNF- α . The results summarized in Table 4 demonstrate

Fig 2. Comparison of the effect of recombinant tumor necrosis factor α (rTNF- α) and lymphotoxin (rTNF- β) on clonogenic cells from two myelogenous leukemia cell lines. Each point represents the mean $\pm$ 1 SD of quadruplicate cultures.

that rTNF- α preferentially inhibits in vitro growth of clonogenic cells as compared with the whole cell population. Similar results were obtained with the highly sensitive KBM-3 cell line (data not shown).

Short-term effect of r-TNF- α on clonogenic cells. We further investigated whether clonogenic cells can be affected by short-term exposure (2 hours) to rTNF- α in doses approximately five to ten times higher than doses causing maximum inhibition of clonal growth in semisolid media. The results observed in two sensitive cell lines are summarized in Table 5. Two-hour exposure inactivated a significant number of clonogenic cells in both cell lines. Viability of cells of both lines, assessed by trypan blue exclusion test, was unaffected by the 2-hour exposure (96% to 98%).

Effect of combination of rTNF- α with rIFN- α or rIFN- γ in clonogenic growth. The addition of increasing doses of rIFN- α or rIFN- γ to a standard dose of rTNF- α affected the rTNF- α -related inhibition only to a limited extent. The results shown in Table 6 show that rIFN- α , but not rIFN- γ , at very high doses (5,000 U/mL) slightly ($P < .05$) potentiated the inhibitory action of TNF in KBM-5 clonogenic cells. At this particular dose level, rIFN- α was not inhibitory itself (data not shown). rIFN- γ appears to decrease the

inhibitory effect of rTNF- α , which is in accord with its growth stimulatory action in the particular passages of these cell lines (data not shown). Similar results were obtained with the EM-2 cell line (Table 6), whereas no enhancement of TNF action by either interferon was found in the TNF-nonresponsive K562 cell line (data not shown).

Receptors for TNF in leukemic cell lines. To investigate whether the heterogeneity in the cellular response to rTNF- α could be due to the heterogeneity in rTNF- α binding sites, we examined the binding of radiolabeled rTNF- α to several cell lines that differed in their sensitivity to rTNF- α in the clonogenic assay (Table 2). The results indicate heterogeneity, both in binding sites per cell and in the affinity of binding sites for the ligand (Table 2). Among all cell lines tested, the correlation to the inhibitory action of TNF was difficult to establish. This indicates that the sensitivity of cells is not simply reflected in the number of binding sites or in ligand affinity, although there was a tendency toward a slightly higher number of binding sites in sensitive cells.

DISCUSSION

The present study revealed a considerable heterogeneity in the sensitivity to rTNF- α of clonogenic cells of six myelogenous leukemia cell lines. No enhancement of clono-

genic cell growth was noted, and one cell line (K562) proved resistant to TNF on continuous exposure of up to 5×10^3 ng/mL. The TNF-sensitive cells responded to increased TNF doses in a characteristic fashion, with a sigmoid dose-response curve on a log/log plot, irrespective of the degree of sensitivity. An important finding was that maximal inhibition was reached at a relatively low concentration of TNF. This may indicate a mode of action compatible with a saturable mechanism.

Analysis of rTNF- α binding properties failed to reveal a consistent pattern to which the sensitivity of cells could be related. This is in agreement with the earlier study of Umeda and co-workers,¹⁶ in which absorption techniques were used, and also with recently reported data on nonhematopoietic cell lines.¹² It suggests that although receptors may be necessary for mediation of TNF action, the magnitude of TNF action is determined by additional as yet unknown cellular mechanisms. The observation that IFN- γ failed to influence the TNF response in either TNF-sensitive or TNF-resistant cells is incongruous with recently published data.¹² In a very few cell systems, however, a synergism, mainly between lymphotoxin (rTNF- β) and IFN- α or IFN- γ , was observed.^{7,9-12} Thus, there may be tissue and cell lineage specificity. Some data indicate that IFN- γ increases the synthesis of TNF

receptors.³⁴ Because of the lack of correlation between TNF receptor numbers, binding affinity, and cell sensitivity, the role of such a mechanism in IFN-TNF cell interactions remains unclear.

Short-term (2 hours) exposure of sensitive leukemic cell lines to moderately high (up to 5×10^3 ng/mL) doses of rTNF- α had no effect on viability of leukemic cells as evaluated by dose-exclusion test. Such short exposure did, however, inhibit subsequent colony formation by clonogenic cells. Although these findings do not support a notion of a direct cytolytic action of TNF in the leukemic cell lines studied, inhibition of cell proliferation as the mechanism underlying its inhibitory action is suggested. This is further supported by the absence of decreased cell viability with increased inhibition of colony formation.

The finding that cell line HL-60 produces TNF when appropriately stimulated²⁰ is suggestive of the role of TNF in a self-regulatory mechanism. In our studies, we showed that the parental, undifferentiated cell line is a very sensitive target for rTNF- α . Whether other AML leukemic cell lines studied here produce TNF is not known and is currently being investigated, as is the relation of sensitivity to the degree of maturation. Production by tumor cells when induced to differentiate of a factor (TNF) that is highly inhibitory to proliferation of clonogenic tumor cells is an

intriguing phenomenon and, if verified in vivo, could have potential therapeutic implications.

Examination of a large number of both mouse and human¹⁻¹⁵ tumor cell lines has revealed considerable heterogeneity in their response to TNF. Because the initial studies used preparations of varying purities derived from various species, it was difficult to compare the relative sensitivities of cell lines used in the different experiments. Furthermore, the sensitivity could vary within each cell line depending on the number of passages and the laboratory in which it was maintained. It was difficult, therefore, to conclude whether a certain response to TNF is related to a particular malignant cell type. In a recent report, however, a heterogeneous response of both human and mouse tumor cell lines to pure rTNF- α was observed.¹²

The purpose of our studies was to examine rTNF- α and IFN- β response in several cell lines derived from one type of hematologic malignancy that had phenotypic features of myelogenous leukemia. We were particularly interested in this tumor type because a TNF message was derived from one AML cell line that was induced to differentiate along the monocytic pathway.²⁰ Thus, the possible antitumor effect could not only be compared with the degree of differentiation of a particular cell line but also with the response of normal hematopoietic progenitor cells. The heterogeneity in the observed response was considerable even within the myelogenous, leukemia-derived cell lines. One line, K562, was resistant to both rTNF- β and rTNF- α , whereas the other lines showed various degrees of sensitivity with no apparent correlation to morphological type. Interestingly, HL-60 was highly sensitive to the antiproliferative effect of rTNF- α , and it was also shown that clonogenic cells—presumably a more primitive category of cells—were more sensitive than the overall population to TNF's inhibitory action. The rTNF- α and rTNF- β resistance of K562 is of particular interest because this cell line is extremely sensitive to natural killer (NK) cell-mediated killing.

Our finding is incongruous with results of a recent report suggesting that rTNF- α may be a major mediator of NK cell action.²⁴ The data show that most myelogenous leukemia cells are very sensitive to TNFs. With the exception of K-562, their sensitivity to rTNF is appreciably higher than that of GM-CFCs³⁸ and comparable to that of clonogenic cells derived from primary acute myelogenous leukemias.³⁸ The availability of cell lines with a defined degree of sensitivity is important for future studies of the mechanism of action and development of resistance to TNFs.

Table 6. Effect of rIFN- α and rIFN- γ on rTNF- α -Induced Inhibition of the Clonogenic Growth of Two Myelogenous Leukemia Cell Lines

Erythrocyte Deformation in Shear Flow: Influences of Internal Viscosity, Membrane Stiffness, and Hematocrit

By Kazunori Kon, Nobuji Maeda, and Takeshi Shiga

The effect of shear force (depending on shear rate and viscosity of extracellular medium) and hematocrit of RBC suspension on RBC deformation was studied quantitatively using a cone-plate rheoscope with various kinds of cells, ie, partially hemolyzed (PH) cells, density-fractionated intact cells, and diamide-treated cells. The deformation index (DI) of ellipsoidally deformed cells was shown to be a function of $\beta\dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^\alpha$, where $\dot{\gamma}\eta_{ex}$ is applied shear stress, η_{ex} and η_{in} are external and internal viscosities, respectively, and α and β are adjustable parameters related to the membrane viscoelastic properties. The increase of suspen-

sion viscosity at higher hematocrits (Hts) generally enhanced the ellipsoidal deformation of cells, in the same manner as increasing the suspending medium viscosity of a diluted cell suspension. The suppressing effect on cell deformation appeared above a certain Ht. When intact cells were mixed with glutaraldehyde-treated, hardened cells, the ellipsoidal deformation of intact cells was disturbed. The suppression of deformation probably occurred through disturbance of laminar flow-lines around intact cells.

© 1987 by Grune & Stratton, Inc.

IT IS WELL KNOWN that blood viscosity, as well as the viscosity of red cell suspension decreases with an increase in a shear rate, because the deformation and orientation of cells reduces hydrodynamic resistance against shear flow.¹ At high shear stresses, RBCs stably orient and elongate, accompanying membrane tank-treading about the cell interior.² The cellular deformation in shear flow is frequently treated by the analogy with that of liquid droplet^{3,4} as described by Taylor⁵ and Cox,⁶ ie, the elongation of cells is enhanced by the increase in viscosity of suspending medium and/or in shear rate. Although the major determinants of the ability of deformation (deformability) of RBCs (ie, intracellular viscosity, membrane stiffness, and cell geometry) have been revealed,⁷⁻¹⁰ the quantitative contribution of these determinants to deformability is not yet clear. In the present study, we assessed quantitatively, over a wide range of shear stress, the influence of intracellular viscosity and membrane stiffness on cellular deformation.

In addition to single cell deformability, to study rheological phenomena of circulating blood, the role of hematocrit should be investigated as an influencing factor on cellular deformation. Rheoscopy¹¹ allows us to observe the cell deformation directly and to measure the degree of cell deformation in a diluted suspension. Direct observation of individual cells is difficult, however, in the suspension of physiological hematocrit (Ht) value because of reduction in light intensity for microscopic observation. Therefore, we prepared partially hemolyzed cells (PH cells) to study the influence of Ht on cellular deformation, ie, we replaced intracellular hemoglobin of intact cells with dextran to increase the transparency of cells and maintain intracellular viscosity.

This article describes: (a) the contribution of viscosity of suspending medium and shear rate on the degree of deformation of various kinds of cells, such as PH cells having different intracellular viscosity, density-fractionated intact cells, and diamide-treated intact cells; (b) the influence of Ht on the cellular deformation over a wide Ht range (from 4% to 55%); and (c) the behavior of intact cells in a mixed suspension of intact cells and glutaraldehyde-treated, hardened PH cells. In these studies, the cell deformation in shear flow is discussed on the basis of an empirical variable depending on the applied shear stress, the internal and external viscosities, and two parameters related to membrane stiffness.

MATERIALS AND METHODS

Preparation of PH Cells

Pink ghosts were prepared by hypotonic hemolysis in a preliminary experiment, but ellipsoidal deformation under uniform shear flow was disturbed. Therefore, we prepared PH cells containing an appropriate amount of dextran by the following procedures.

Freshly drawn heparinized blood from healthy donors was centrifuged to remove plasma and buffy coat. The packed cells were then washed three times with an isotonic HEPES buffer (115 mmol/L of NaCl, 50 mmol/L of HEPES, 6 mmol/L of glucose, 5 mmol/L of KCl, pH 7.4). The washed cells were suspended in the isotonic HEPES buffer containing 38 μ mol/L of L- α -lysophosphatidylcholine, palmitoyl (LPC, Sigma Chemical, St Louis) at a Ht of 45% (the RBCs changed from discocytes to spherocytocytes in the presence of LPC). After the suspension was allowed to stand for 5 minutes on ice, it was centrifuged to obtain packed LPC-treated cells. Two kinds of PH cells, having low internal viscosity (light PH cells) and high internal viscosity (heavy PH cells), were prepared by incubating LPC-treated cells in hypotonic dextran solutions as follows.

Light PH cells. In step 1, 1 mL of the LPC-treated packed cells was suspended in 9 mL of ice-cooled hypotonic HEPES buffer (10 mmol/L of HEPES, 1 mmol/L of KCl, 1 mmol/L of glucose, 2 mmol/L of EGTA, 5 mmol/L of MgSO₄, 0.8 mmol/L of ATP; pH 7.4, 30 mOsm/kg) containing 7% Dextran T-40 (Pharmacia Fine Chemicals, Uppsala, Sweden) and was incubated for 5 minutes on ice with gentle stirring (designated as step-1 suspension). In step 2, 9 mL of the same hypotonic 7% dextran solution was added to the step-1 solution, and the suspension was stirred gently for 5 minutes. In step 3, to return the isotonicity, 1.44 mL of a hypertonic HEPES buffer (1,150 mmol/L of NaCl, 500 mmol/L of HEPES, 60 mmol/L of glucose, 50 mmol/L of KCl; pH 7.4) was added to the

step-2 suspension. In step 4, to remove LPC from cells, 18 mL of the isotonic HEPES buffer containing 1.5% bovine serum albumin (BSA, fraction-V, purchased from Armour Pharmaceutical, Kankakee, IL) was added to the step-3 suspension, followed by incubation of the suspension for 1 hour at 37 °C. During the incubation, resealing of cells was accomplished. In step 5, the resulting PH cells were washed once with an isotonic 7% dextran solution (100 mmol/L of NaCl, 50 mmol/L of HEPES, 6 mmol/L of glucose, 5 mmol/L of KCl; pH 7.4) to remove a minute amount of membrane fragment and washed twice with the isotonic HEPES buffer.

Heavy PH cells. The above procedures for the preparation of light PH cells were followed with a minor modification: In step 2, instead of the hypotonic 7% dextran solution, 9 mL of the hypotonic HEPES buffer containing 30% dextran was added to the step-1 suspension.

Preparation of Density-Fractionated Intact Cells

Intact cells were fractionated by density-gradient centrifugation.¹² An isotonic suspension of Percoll (Pharmacia) in the HEPES buffer was used: 75.6% Percoll to obtain low-density cells and 82.8% Percoll to obtain high-density cells. One milliliter of packed cells was poured on 13.5 mL of Percoll medium and then spun at 7,000 g for 20 minutes at 20 °C. The low-density cells (10% to 15% of all cells) gathered in the upper half of the tube (in 75.6% Percoll) while the high-density cells (30% of all cells) sedimented in the lower half of the tube (in 82.8% Percoll). The low-density cells and high-density cells can be assigned to young and aged cells, respectively.^{13,14} The fractionated cells were washed three times with the isotonic HEPES buffer to remove Percoll. The fractional percentage was calculated on the basis of hemoglobin concentration.

Preparation of Diamide-Treated Hardened Cells (Diamide-Treated Cells)

The fractionated low-density cells were suspended in the isotonic HEPES buffer and incubated with various concentrations of diamide (diazene dicarboxylic acid bis(*N,N*-dimethylamide, Sigma) for 30 minutes at 37 °C (Ht 10%).¹⁵ After incubation, cells were washed three times with the isotonic HEPES buffer.

Preparation of Glutaraldehyde-Treated, Hardened PH Cells (GA-Treated PH Cells)

Light PH cells were suspended in the isotonic HEPES buffer containing 0.1% glutaraldehyde at a Ht of 10% and incubated for 30 minutes at 37 °C with gentle stirring. To remove unreacted glutaraldehyde, cells were washed three times with the isotonic HEPES buffer.

Determination of Mean Corpuscular Volume (MCV)

MCV was determined from the number of cells measured by an automatic counter (Model CC-110, Toa Electric, Tokyo), and the packed cell volume was determined by the method of England and Down,¹⁶ as follows. Cells were washed with the isotonic HEPES buffer containing 1.5% BSA and suspended in the same solution. Ten microliters of ¹³¹I-labeled BSA solution (150 μ Ci/mL) were added to 5 mL of the cell suspension (Ht 50%). The radioactivities of supernatant and sedimented fraction were measured by an autowell γ counter (ARC-605, Aloka, Tokyo) after centrifugation for 10 minutes at 6,000 g with a microhematocrit tube using a microhematocrit centrifuge (Model KH-120, Kubota, Tokyo) and the packed cell volume was calculated after the volume of medium trapped among cells was corrected.

The Ht value of the cell suspension was determined after correcting the trapped medium volume. For the GA-treated PH cell

suspension, the Ht was calculated from the number of cells in the suspension and the MCV of original cell before GA treatment.

Electrophoretic Analysis of Membrane Proteins

The polyacrylamide gel electrophoresis (PAGE) in 1% sodium dodecyl sulfate (SDS) was performed on a slab gel.¹⁷ The densitometric scanning of Coomassie brilliant blue R-250-stained gel was performed by a densitometer (Dual-wavelength TLC Scanner, CS-900, Shimadzu, Kyoto, Japan). After diamide treatment, the degree of cross-linking of membrane proteins was estimated by the method of Maeda and colleagues.¹⁵

Determination of Amounts of Membrane Lipids

To estimate the loss of membrane lipids during the preparation of PH cells, the amounts of cholesterol and total phospholipids were determined by the method of Zlatkis and Zak¹⁸ and Bartlett,¹⁹ respectively.

Measurement of Cellular Deformation

Cellular deformation was observed at 25 °C with a cone-plate rheoscope¹¹ constructed in our laboratory^{15,20} combining an inverted microscope (Model IMT, Olympus Optics Co., Tokyo), a transparent 0.8° cone-plate viscometer (Model B, Tokyo Keiki) and a flashlight (Model MS-230, Sugawara, Tokyo). Two experimental protocols were used as follows. First, cells were suspended in isotonic dextran solutions to make a Ht of 0.4% to observe cell deformation in a diluted suspension. The shear rates were changed stepwise in the range of 75.2 to 752 s⁻¹. The dextran concentration was varied in the range of 7.5% (4.0 cP) to 20% (18.3 cP). Second, for observation of the cellular deformation at higher Hts, cells were suspended in either isotonic dextran solutions (6% or 10%) or plasma with varying Ht (4% to 55%), and a constant shear rate (752 s⁻¹) was applied.

The osmolality of dextran solutions was adjusted with NaCl by using a Halbmikro osmometer (Type M, Knauer, FRG) after dissolving an appropriate amount of dextran in a hypotonic HEPES buffer (50 mmol/L of HEPES, 5 mmol/L of KCl, 6 mmol/L of glucose). The degree of deformation of stably oriented and deformed cells was expressed by the DI, defined by $DI = (L - B)/(L + B)$, where L and B are the lengths of long and short axes of ellipsoidally deformed cells.³ For each sample, DIs of 60 to 80 cells were measured.

Measurement of Viscosity

To measure the viscosity of hemolysate and cell suspension, a cone-plate viscometer (Model E, Tokyo Keiki) was used at 25 °C. For measurement of intracellular viscosity, the hemolysates of both fractionated intact cells and PH cells were prepared. The packed cells were suspended in 3 vol of hypotonic HEPES buffer (30 mOsm/kg, 5 mmol/L of HEPES, 10 mmol/L of NaCl; pH 7.4). After membrane components were removed by centrifugation (10,000 g for 20 minutes), the hemolysate was concentrated by ultrafiltration (using a collodion bag; SM13200, Sartorius-Membranefilter GmbH, Göttingen, FRG) until the hemoglobin concentration of the hemolysate reached that of the intracellular hemoglobin concentration of original cells. The viscosity of hemolysate of intact cells agreed with the reported value.²¹

RESULTS

Characterization of PH Cells

To facilitate the optical transparency of cell suspension and to avoid the decrease of internal viscosity, PH cells were prepared in the hypotonic dextran solution. Intact cells

resisted hypotonic hemolysis in the presence of dextran. Thus, to enhance hemolysis, cells were pretreated with LPC. By suspending LPC-treated cells in the hypotonic solution of different concentrations of dextran, the internal viscosity of PH cells could be varied. After resealing, LPC in the cell membrane was removed by washing with BSA solution and the cell shape could be easily reverted to biconcave disc. Although progressive loss of membrane materials caused by increasing LPC concentration has been reported,²² at a low concentration such as was used in the present study, no loss of cholesterol and phospholipids of either LPC-treated cells or PH cells was detected.

In this study, two kinds of PH cells, heavy and light, were prepared. The typical data about the properties of these cells are summarized in Table 1, together with data about density-fractionated intact cells for comparison. PH cells deformed to the flat ellipsoid with unequal axial lengths in shear flow as well as intact cells did, as reported by Suda and co-workers.²⁰ Thus, the degrees of deformation are expressed by DI in Table 1.

Deformation of Cells in Diluted Suspension

To investigate the influence of viscosity of suspending medium and shear rate on the degree of deformation, the DIs of cells suspended in the isotonic solution of various concentrations of dextran (hematocrit, 0.4%) were measured at various shear rates. Fischer and colleagues³ have shown that the DI of intact cells is a function of $\dot{\gamma}\eta^{1.5\pm0.2}$, where $\dot{\gamma}$ and η are shear rate and medium viscosity, respectively. In the present study, taking the intracellular viscosity into account, the variable $\dot{\gamma}\eta^{1.5\pm0.2}$ is modified to $\dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^\alpha$, where η_{ex} is the viscosity of the suspending medium, η_{in} is the intracellular viscosity, and α is the adjustable parameter.

PH cells. The DIs of light PH cells, at various shear rates and viscosities of suspending medium, are shown in Fig 1A. At certain DIs, the plots of $\log \dot{\gamma}\eta_{ex} \nu \log (\eta_{ex}/\eta_{in})$ shown in Fig 1B give parallel straight lines with the same slope (-0.6), where interpolated $\dot{\gamma}$ values were read at the crossing points on lines a through d of Fig 1. Thus, DI is expressed as a function of $\dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^{0.6}$. In Fig 2A, all DIs of light PH cells and heavy PH cells are plotted against $\dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^{0.6}$, and all points lie on the same curve in spite of the difference in η_{in} between light and heavy PH cells.

Fig 1. (A) Dependence of deformation index (DI) of light partially hemolyzed (PH) cells on the shear rate in the isotonic dextran solutions. Dextran concentration: 7.5% (Δ , 4.0 cP), 8.6% (∇ , 4.7 cP), 10% ($\blacksquare$, 5.1 cP), 11% ($\blacktriangle$, 6.1 cP), 12% ($\bullet$, 6.7 cP), 14% (∇ , 8.8 cP), 16% ($\square$, 11.5 cP), 18% (Δ , 14.5 cP), and 20% ($\circ$, 18.3 cP). DI is represented by mean $\pm$ SD of 60 to 80 cells. Lines a through d represent DI = 0.40, 0.31, 0.23, and 0.16, respectively; $\dot{\gamma}$ values at each DI value were estimated. (B) Logarithmic plot of shear stress ($\dot{\gamma}\eta_{ex}$) ν (suspending medium viscosity/intracellular viscosity) (η_{ex}/η_{in}). Data and symbols are the same as in A. The points on line a give a DI value of 0.40, on line b a DI value of 0.31, on line c a DI value of 0.23, and on line d a DI value of 0.16. The lines are drawn by linear regression analysis (mean $\pm$ SD of these slope = -0.60 ± 0.03).

Intact cells. Intracellular viscosity is well known to increase with cell aging. Therefore, intact cells were fractionated with Percoll to minimize the variation of intracellular viscosity. The same value of α was obtained for both low-density cells and high-density cells as that for PH cells in the plot $\log \dot{\gamma}\eta_{ex} \nu \log (\eta_{ex}/\eta_{in})$ (not shown). The curve of DI $\nu \dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^{0.6}$ of intact cells slightly shifts upward (Fig 2B) as compared with that of PH cells (dotted line is the curve for PH cells shown in Fig 2A). To fit these curves on the same line, another parameter β must be introduced; DI is then expressed as a function of $\beta\dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^{0.6}$. Adopting $\beta = 1$ for the intact cells, β for PH cells should be reduced to 0.7.

Table 1. Hematological Indices and Deformability of PH Cells and Fractionated Intact Cells

Cells	MCV (μm^3)	[Hb] _{in} * (mmol/L Cell)	$\eta_{in}\dagger$ (cP)	DI $\ddagger$	
				$\dot{\gamma} = 150 \text{ s}^{-1}$	$\dot{\gamma} = 376 \text{ s}^{-1}$
PH					
Light	96.0	2.58	3.5 (2.8)	0.35 ± 0.05	0.47 ± 0.02
Heavy	75.2	3.73	9.8 (5.0)	0.27 ± 0.05	0.41 ± 0.04
Intact§					
Low density	89.0	5.05	10.3	0.31 ± 0.04	0.44 ± 0.05
High density	81.5	6.20	20.4	0.22 ± 0.05	0.36 ± 0.05

PH, partially hemolyzed; MCV, mean corpuscular volume.

*Intracellular hemoglobin concentration.

$\dagger$ Intracellular viscosity. The value in parentheses is the viscosity of hemolysate (prepared from intact cells) having the same hemoglobin concentration as that of PH cells.

$\ddagger$ Deformation index (DI) was measured at shear rates ($\dot{\gamma}$) of 150 and 376 s⁻¹ when cells were suspended in 20% dextran solution (18.3 cP).

§Intact cells were fractionated by density gradient (described in Materials and Methods section).

Fig 2. (A) Plot of deformation index (DI) $\nu \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$ of partially hemolyzed (PH) cells. Light PH cells (○) were suspended in isotonic dextran solutions of 7.5% (4.0 cP) to 20% (18.3 cP), and heavy PH cells (●) were suspended in solutions of 11% (6.1 cP) to 20%. DI was measured at shear rates of 75.2, 150, 376, 752 s⁻¹. Data of light PH cells are the same as in Fig 1A. DI is represented by a mean of 60 to 80 cells. (B) Plot of DI $\nu \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$ of intact cells. Fractionated low-density cells (○) were suspended in isotonic dextran solutions of 14% (8.8 cP) to 20% (18.3 cP), and fractionated high-density cells (●) were suspended in solutions of 16% (10.8 cP) to 20%. DI was measured at the same shear rates as in Fig 2A. The dotted line is the regression curve for PH cells shown in Fig 2A. DI is represented by a mean of 60 to 80 cells.

This fact implies that PH cells are less deformable than intact cells; presumably, the PH cell membrane would be impaired during preparation of PH cells.

Diamide-treated cells. Diamide has been shown to induce cross-linking of membrane proteins to decrease cellular deformability.^{15,23} When a high concentration of diamide is applied, a buckling pattern (furrows parallel to the flow direction) appears²⁴ and, in addition, hemoglobin is modified.¹⁵ Therefore, to study the influence of cross-linking of membrane proteins (mainly spectrin) on deformation, the concentration of diamide must be lowered to <1 mmol/L (no buckling pattern was detected).

DIs of diamide-treated cells were measured in the dextran solution from 15.5% (11.0 cP) to 20% (18.3 cP). The parameter α for diamide-treated cells was dependent on the degree of cross-linking, as estimated from the plot of $\log \dot{\gamma} \eta_{ex} \nu \log (\eta_{ex}/\eta_{in})$ (not shown). In Fig 3A, DIs are plotted against $\beta \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^\alpha$, with appropriate α values for cells treated with diamide of various concentrations whereas β is fixed at unity. Furthermore, adopting an appropriate value of β for each curve shown in Table 2, all points can be brought on the same curve (Fig 3B), which curve agrees with the curve for intact cells (Fig 2B), ie, both α and β decrease as the cross-linking proceeds.

Deformation of PH Cells Suspended in 6% Dextran Solution at Various Hts

Light PH cells. The rheoscopic flash photographs of light PH cells in relatively low Ht range (4% to 25%) at $\dot{\gamma} = 752$ s⁻¹ are shown in Fig 4 (line B). The ellipsoidal deformation becomes clear as hematocrit increases. This monotonous

Fig 3. Plot of deformation index (DI) $\nu \beta \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^\alpha$ for diamide-treated cells. (A) The parameter α is varied whereas β is fixed at unity. Fractionated low-density cells were treated with diamide. Diamide concentration: 0 mmol/L (○), 0.55 mmol/L (●), 0.65 mmol/L (△), 0.95 mmol/L (▲). Cells were suspended in isotonic dextran solutions of 15.5% (11.0 cP) to 20% (18.3 cP), and DI was measured at shear rates of 75.2, 150, 376, and 752 s⁻¹; α values for cells treated with 0, 0.55, 0.65, and 0.95 mmol/L of diamide are 0.6, 0.5, 0.35, and 0, respectively. DI is represented by a mean of 60 to 80 cells. (B) Both parameters α and β are altered. Data and symbols are the same as in Fig 3A; β values for cells treated with 0, 0.55, 0.65, and 0.95 mmol/L of diamide are 1, 0.7, 0.5, and 0.4, respectively (α values are the same as in Fig 3A). The dotted line is the regression curve of DI $\nu \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$ of intact cells shown in Fig 2B. The degrees of cross-linking of spectrin of cells treated with different concentrations of diamide are shown in Table 2.

increase of deformation is due to increased suspension viscosity, from 3.4 cP (Ht = 4%) to 4.2 cP (Ht = 25%). When DIs are plotted against $\dot{\gamma} \eta_{sp} (\eta_{sp}/\eta_{in})^{0.6}$ (Fig 5), where η_{sp} is the suspensin viscosity, DIs lie on the DI $\nu \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$ curve of light PH cells shown in Fig 2A. Therefore, the increase of suspensin viscosity acts on cellular deformation in the same manner as the increase of viscosity of the dextran solution.

On the other hand, at higher Hts (>25%), DI measurement was impossible due to cell crowding. At a Ht of 45%, however, cells were photographically observed to deform to flat ellipsoid but variously distorted shapes and orient with their long axes parallel to the flow direction (Fig 4, line B).

Heavy PH cells. The ellipsoidal deformation could not be observed for heavy PH cells. Presumably, the value of $\dot{\gamma} \eta_{sp} (\eta_{sp}/\eta_{in})^{0.6}$ was not high enough to induce such deformation (eg, $\dot{\gamma} \eta_{sp} (\eta_{sp}/\eta_{in})^{0.6} = 19$ dynes/cm² at a Ht of 20%) due to the higher intracellular viscosity of heavy PH cells as compared with that of light PH cells.

Table 2. α and β Values of Diamide-Treated Cells

Diamide* (mmol/L)	Cross-linking† (%)	α	β
0	0	0.6	1
0.55	27.4	0.5	0.7
0.65	33.3	0.35	0.5
0.95	46.7	0	0.4

*Diamide concentration for diamide treatment of intact cells.

†Percentage of spectrin polymerization (described in Materials and Methods section).

Fig 4. Deformation of light partially hemolyzed (PH) cells in the suspension of various hematocrits. Cells were suspended in 10% dextran solution (5.1 cP, line A), 6% dextran solution (3.3 cP, line B), and plasma (1.8 cP, line C). Cell deformation was observed at a shear rate of 752 s^{-1} . Hematocrit (Ht) of the suspension ranges from 4% to 45%.

Deformation of PH Cells Suspended in 10% Dextran Solution at Various Hts

Light PH cells. In 10% dextran solution, light PH cells demonstrate advanced ellipsoidal deformation as compared with those in 6% dextran solution at lower Hts (<25%) as shown in Fig 4 (line A). When DIs are plotted against $\dot{\gamma}\eta_{sp}(\eta_{sp}/\eta_{in})^{0.6}$, however, DI decreases from 0.28 to 0.23

Fig 5. Effect of increasing hematocrit of partially hemolyzed (PH) cell suspension on deformation index (DI). Light PH cells were suspended in isotonic dextran solutions of 6% (3.3 cP, $\circ$) and 10% (5.1 cP, Δ). Heavy PH cells were suspended in 10% dextran solution ($\blacktriangle$). Deformation index (DI) was measured at a shear rate of 752 s^{-1} . Hematocrits of the suspension of light PH cells in 6% dextran solution were 4%, 8%, 15%, 20%, and 25%. Those of light PH cells in 10% dextran solution and heavy PH cells in 10% dextran solution were 4%, 8%, 15%, and 20%. DI is given as mean $\pm$ SD ($n = 60$ to 80). The dotted line is the regression curve of $\text{DI} \propto \dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^{0.6}$ of PH cells shown in Fig 2A.

despite the increase in $\dot{\gamma}\eta_{sp}(\eta_{sp}/\eta_{in})^{0.6}$ from 60 dynes/cm² (at Ht = 4%, $\eta_{sp} = 5.6$ cP) to 80 dynes/cm² (at Ht = 20%, $\eta_{sp} = 7.1$ cP) as shown in Fig 5. In Fig 4 (line A), a photograph at Ht = 45% is also shown, in which distorted ellipsoidal deformation is observed.

Heavy PH cells. Although the intracellular viscosity was high, the ellipsoidal deformation was induced due to high viscosity of the suspending medium. In the Ht range of 4% to 20%, as shown in Fig 5, DIs lie on the $\text{DI} \propto \dot{\gamma}\eta_{ex}(\eta_{ex}/\eta_{in})^{0.6}$ curve of light PH cells shown in Fig 2A. The suspension viscosity changes from 5.9 cP (Ht = 4%) to 7.6 cP (Ht = 20%).

Deformation of PH Cells Suspended in Plasma at Various Hts

Light PH cells. Cells deform to variously distorted discs at the lower Ht (<25%); however, distorted ellipsoidal deformation is conspicuous at Ht = 45%, as shown in Fig 4 (line C), at which cells deform to the same shape as that of light PH cells in 6% and 10% dextran solutions.

Heavy PH cells. Although the extracellular viscosity was low (1.8 cP), cells deformed but distorted in various shapes at the higher Ht range (35%, 45%, and 55%).

Deformation of Intact Cells in the Coexistence of Undeformable Cells

To investigate the influence of undeformable cells on the behavior of deformable cells in shear flow, a small amount of fractionated low-density intact cells (tracer cells) was mixed with either a larger amount of light PH cells (deformable cells) or GA-treated PH cells (light PH cells treated with GA, undeformable cells), and deformation of tracer cells was observed. GA-treated PH cells could not deform, and they oriented randomly in shear flow. Cells were suspended in

16.7% dextran solution (12.7 cP) in which the Ht of tracer cells was kept constant (0.4%), and the Ht of light PH cell and GA-treated PH cell suspensions varied from 2.1% to 6.3%. On the flash-photographs, the intact tracer cells could be distinguished from the light PH or GA-treated PH cells by differences of cell shape and of darkness (due to higher hemoglobin concentration). The ellipsoidal deformation of intact cells was not affected in the deformable light PH cell suspension (Fig 6B,C,D), nor in the diluted GA-treated PH cell suspension (Ht = 2.1%) (Fig 6E). When the amount of the GA-treated PH cells was increased, however (to Ht = 6.3%), the ellipsoidal deformation was remarkably disturbed (Fig 6F,G).

DISCUSSION

Contribution of Intracellular Viscosity and Membrane Stiffness to Cellular Deformation

Increased viscosity of suspending medium is well known to enhance the deformation of RBCs, although the degree of deformation is influenced by intracellular viscosity. Pfafferoth and co-workers²⁵ showed that the differences between young and old cell deformation were eliminated if the DI was plotted as a function of the ratio of intracellular/extracellular viscosities for various shear stresses.

In the present study, we demonstrated the effect of extracellular/intracellular viscosities and membrane stiffness on the cellular deformation and revealed that DI is a function of $\beta \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^\alpha$. For various kinds of cells, $\alpha = 0.6$ is unanimously applicable (Fig 2A,B). Taking $\beta = 1$ for the intact cells, β should be reduced to 0.7 for PH cells to fit the data of PH cells on the same curve, $DI \propto \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$, of intact cells, indicating that PH cells are less deformable than intact cells. A remarkable difference of cell volume between light and heavy PH cells is detected (Table 1), whereas the surface area of these cells remains constant (because no loss of membrane lipids is detected). This may affect the cellular deformation through the change of surface/volume (S/V) ratio which is one of the determinants of deformability. No difference, however, in the relation $DI \propto \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$

between light and heavy PH cells (Fig 2A) suggests that such change of S/V ratio does not shift the curves $DI \propto \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$ throughout. Therefore, the decrease in β of PH cells is presumably due to the increased membrane stiffness caused by changes in membrane integrity.

Although the intracellular viscosity of light PH cells is about half that of fractionated low-density cells, DIs of light PH cells are close to that of fractionated low-density cells at given shear stresses (Table 1), because the effect of lowered intracellular viscosity of PH cells on DIs is canceled by the increased membrane stiffness.

Age-related changes in membrane viscoelastic properties were reported.^{13,14,26,27} In this study, no difference in the $DI \propto \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^{0.6}$ curve between low-density cells and high-density cells was detected (Fig 2B). This result may imply that the age-dependent changes in membrane properties have no significant effect on the ellipsoidal deformation in shear flow.

The influence of cross-linking of membrane proteins is remarkable. When the intact cells (of low density) are treated with diamide, two parameters, α and β , must be reduced (Table 2) to bring all data to the same curve in the plot of $DI \propto \beta \dot{\gamma} \eta_{ex} (\eta_{ex}/\eta_{in})^\alpha$ (as shown in Fig 3).

The mechanical property of the membrane is physically expressed by the three intrinsic material constants of membrane, ie, elastic modulus, area compressibility, and membrane viscosity.^{28,29} The alteration of area compressibility would not be detectable in the present method, because discocytes deform easily at constant area but strongly resist change in area.³⁰ Nash and Meiselman demonstrated that the ghost has a greater shear modulus but a similar membrane viscosity.³¹ Their result may correspond to the present result, ie, the partial hemolysis causes the change in β but not in α . The parameter β may thus be related to the shear modulus. According to dimensional analysis, β should have a dimension of $(\text{dynes/cm}^2)^{-1}$. Therefore, a reciprocal of β would express the relative shear modulus, and the shear modulus of PH cells may be ~ 1.4 times higher than that of intact cells. The diamide treatment is also known to increase the shear modulus²⁴ and may cause increased membrane

Fig 6. Deformation of intact cell (fractionated low-density cell) in mixed suspension. Fractionated low-density cells (tracer cells) were suspended in 16.7% dextran solution (12.7 cP; the hematocrit of the tracer cells was adjusted to 0.4%) with either light partially hemolyzed (PH) cells or glutaraldehyde (GA)-treated PH cells. The deformation of tracer cells was observed at a shear rate of 752 s^{-1} . (A) Only tracer cells present in the suspension. (B through D) Tracer cells are mixed with light PH cells. Hematocrits of light PH cells in the suspensions of B, C, and D, are 2.1%, 4.3%, and 6.3%, respectively. (E through G) Tracer cells are mixed with GA-treated PH cells. Hematocrits of GA-treated PH cells in the suspensions of E, F, and G are 2.1%, 4.3%, and 6.3%, respectively.

viscosity³² by restricting the flexibility of cytoskeleton. This may lead to the decrease of two parameters, α and β .

Ht Dependency of Cellular Deformation

The shear rate applied in this study ($\dot{\gamma} = 752 \text{ s}^{-1}$) corresponds to the calculated wall shear rates in artery and capillary ($\sim 1,000 \text{ s}^{-1}$), assuming that Poiseuille flow³³ and the behavior of PH cells in flow is similar to that of intact cells. Therefore, the present study gives information on RBC behavior in blood flow.

The quantitative measurement of PH cell deformation is possible up to the Ht value of $\sim 20\%$. When the light and heavy PH cells are suspended in 6% and 10% dextran solutions, respectively, progressive deformation due to increase of suspension viscosity is observed. The increase in suspension viscosity owing either to increasing Ht or dextran concentration induces the same degree of ellipsoidal deformation (Fig 5). However, the value of $\dot{\gamma}\eta_{sp}(\eta_{sp}/\eta_{in})^{0.6}$ is below $\sim 20 \text{ dynes/cm}^2$, both light and heavy PH cells suspended in any medium cannot deform, because at low value of $\dot{\gamma}\eta_{sp}(\eta_{sp}/\eta_{in})^{0.6}$, the shear force is not enough to induce the deformation. On the other hand, DI of light PH cells suspended in 10% dextran at $\dot{\gamma}\eta_{sp}(\eta_{sp}/\eta_{in})^{0.6} = 80 \text{ dynes/cm}^2$ is smaller than that at $\dot{\gamma}\eta_{sp}(\eta_{sp}/\eta_{in})^{0.6} = 60 \text{ dynes/cm}^2$ as shown in Fig 5. In this decline phase, the ellipsoidal deformation is rather suppressed, probably because the cell crowding disturbs the uniform stream lines. Concerning the effect of Ht, Kon and Kon³⁴ have shown that the degree of deformation and orientation is suppressed as the Ht is increased above a certain value depending on extracellular viscosity; ie, the critical Ht value, at which the suppressing effect begins, shifts toward a lower Ht as the extracellular medium increases in viscosity. At higher Hts ($>25\%$), quantitative measurement of DI is not possible, even with PH cells. The degree of deformation of PH cells in plasma is qualitatively the same as that in 6% and 10% dextran solutions at a Ht of 45%, however. The ellipsoidal deformation of intact cells at a higher Ht is shown by Fischer and Schmid-Schönbein.² The

present result is explained as follows: The cellular deformation of PH cells in plasma is progressively induced with increasing Ht, but in 6% and 10% dextran solutions the suppressive mechanism becomes operative on cells at the higher Ht.

The influence of cell concentration was described by Goldsmith and Marlow³⁵; ie, the progressive deformation of tracer amount of intact cells in the ghost cell suspension (intact cells did not deform to ellipsoid but to irregularly distorted ellipsoid) with increasing ghost concentration; thus, they have proposed that the collision between cells induces such irregular deformation. In the present study, the fractionated low-density cells deformed to ellipsoid in light PH cell suspension but not in GA-treated PH cell suspension. This phenomenon may be due to the disturbance of laminar flow caused by tumbling of the hardened cells, which consequently reduces the effective shear stress acting on intact cells. Tumbling of rigid discs in Poiseuille flow is known,⁴ and a similar disturbing effect of hardened cells on intact cell deformation was reported by Kon and coworkers.³⁶ Therefore, the ellipsoidal deformation of intact cells is maintained by ellipsoidal deformation of surrounding cells.

In short, the present study reveals that: (a) The degree of deformation of cells is determined by the applied shear stress ($\dot{\gamma}\eta_{ex}$), the viscoelastic membrane properties (reflected on the parameters α and β), and the ratio of suspending medium viscosity to internal viscosity (η_{ex}/η_{in}); and (b) increasing suspension viscosity (η_{sp}) by raising Ht generally enhances cellular deformation, but above a certain Ht deformation is suppressed. At physiological Ht, cellular deformation is mainly influenced by Ht, and the contribution of viscosity of extracellular medium is not significant.

ACKNOWLEDGMENT

We wish to thank Professor Syoten Oka for valuable discussions and Misuzu Sekiya and Takuya Taniguchi for their technical assistance with experimental procedures.

Lack of Association Between Abnormalities of the Chromosome 9 Short Arm and Either "Lymphomatous" Features or T Cell Phenotype in Childhood Acute Lymphocytic Leukemia

By Andrew J. Carroll, Robert P. Castleberry, and William M. Crist

In childhood acute lymphocytic leukemia (ALL), abnormalities in the short (p) arm of chromosome 9, particularly those leading to the loss of material in the p21-p22 region, may be associated with bulky disease at diagnosis (so-called "lymphomatous" ALL) and a T cell immunophenotype. To assess these associations further, we reviewed the clinical and laboratory data for 100 consecutively evaluated children with ALL who had successful cytogenetic studies. From analysis of clinical and laboratory features, 8 of the 100 patients were classified as having lymphomatous ALL. Seven of the 100 patients had aberra-

tions involving the 9p arm or were missing an entire chromosome 9. The prevalence rate of 9p abnormalities in cases of lymphomatous ALL was not significantly different from that in cases without lymphomatous features (1 of 8 v 6 of 92, $P = .62$). Moreover, all seven patients with 9p abnormalities had the common ALL phenotype. These data suggest that although 9p abnormalities in childhood ALL occur frequently, there is no consistent association with either the occurrence of lymphomatous clinical features or the presence of T cell disease.

© 1987 by Grune & Stratton, Inc.

THE CHROMOSOME complement of the leukemic clone is now recognized as an important prognostic variable in childhood acute lymphocytic leukemia (ALL).¹ Several clinically and/or immunologically defined subgroups of ALL have been associated with nonrandom cytogenetic abnormalities, including translocations such as t(4;11) in undifferentiated acute leukemia, t(8;14) in B cell ALL, t(1;19) in pre-B cell ALL,^{2,3} and t(11;14) in T cell ALL.³ Each of these is associated with a poor prognosis.

Kowalczyk and Sandberg⁴ identified a small, potentially important subgroup of patients with ALL, characterized by loss of material from the short arm of chromosome 9 (9p-), who typically were diagnosed with lymphadenopathy, splenomegaly, high leukocyte counts, and T cell markers on the surface of their leukemic blasts. More recently, Chilcote and colleagues⁵ proposed that loss of chromosomal material at 9p21-22 might be characteristic of patients with "lymphomatous" ALL. These children also had bulky extramedullary leukemia, often a T cell immunophenotype, and responded poorly to treatment. We therefore analyzed the clinical data for 100 consecutively evaluated children with ALL who had successful cytogenetic studies. We found no evidence to support the proposed association between 9p abnormalities and either lymphomatous clinical features or T cell disease.

MATERIALS AND METHODS

Patients. The study population was derived from children with ALL diagnosed and treated at The Children's Hospital of Alabama from 1978 through 1985. Informed consent, in accordance with institutional and FDA guidelines, was obtained prior to bone marrow aspiration. Clinical data from 100 consecutive patients with successful cytogenetic studies were analyzed. Lymphomatous ALL was defined on the basis of at least one clinical and one laboratory feature from the following list: discrete lymphadenopathy with nodes >3 cm in diameter or matted nodes >5 cm collectively; splenomegaly below the umbilicus; a mediastinal mass equal to more than one-third of the thoracic diameter; hemoglobin concentration >10 g/dl; leukocyte count >50,000/ μ l and E rosette positivity (E+) >25%. Patients were treated according to protocols of the Pediatric Oncology Group.

Immunologic characterization. After separation on a Ficoll-Hypaque gradient, leukemic marrow cells were evaluated by standard techniques for surface immunoglobulins (sIg),⁶ cytoplasmic immunoglobulins (cIg),⁷ and receptors for sheep erythrocytes.⁸ In

pre-B or B cell ALL, >10% of blasts expressed cIgs or sIgs, respectively. A case was considered E rosette positive if >40% of blasts formed heat stable E rosettes. The common ALL antigen (CALLA) was identified by microcytotoxicity with heteroantisera as previously described.⁹ CALLA positivity was present if blasts exhibited >40% lysis above control cells.

Chromosome analysis. Cells from bone marrow aspirates were processed directly and/or were subjected to short-term culture. For direct chromosome preparations, a fresh bone marrow aspirate (≤ 0.5 mL) was immediately placed into a sterile centrifuge tube containing 10 mL of 0.075 mol/L of KCl and colcemid (0.06 μ g/mL) and allowed to incubate at room temperature for 30 minutes. For short term culture, a bone marrow aspirate (≤ 0.5 mL) was placed in 10 mL of RPMI 1640 supplemented with 10% fetal calf serum (FCS) for 24 hours at 37 °C and then exposed to colcemid (0.06 μ g/mL for 2.5 hours at 4 °C. Routine methods were used for culture harvest, slide preparation, and GTG-banding. Karyotypic designations were assigned according to the International System for Human Cytogenetic Nomenclature.¹⁰

RESULTS

Sixty-one of the 100 cases studied had an acquired, cytogenetically abnormal leukemic clone. Seven (cases 1 through 7, Tables 1 and 2) had aberrations involving the short arm of chromosome 9; unbalanced rearrangements resulting in the loss of 9p material were noted in five (cases 1 and 4 through 7). Case 3 had a balanced translocation involving 9p22, and case 2 was missing an entire 9 chromosome. None of the six translocations involving 9p were identical. The source of the material that was translocated to

*Spleen tip palpable below the umbilicus.

†Greater than one-third the thoracic diameter.

‡Inconclusive.

9p could be identified in four cases and involved chromosomes 10, 12p, 12q, and 13.

Eight children were diagnosed with lymphomatous ALL (cases 7 through 14, Tables 1 and 2). Their average age was 11.5 years as compared with 6.7 years for patients without lymphomatous characteristics. Notable clinical features included a leukocyte count $>50,000/\mu\text{L}$ in 5 cases, E rosette positivity in 5, clinically significant lymphadenopathy in 4, mediastinal mass in 3, and massive splenomegaly in 2.

Immunophenotypes were pre-B cell (1); B cell (1); non-B, non-T, non-pre-B (1); and T cell (5). The proportion of T cell disease was predictably higher in the lymphomatous subset as compared with the remainder of the patient population (5 of 8, 63% v 6 of 92, 7%). The overall distribution of cases according to immunophenotype was non-B, non-T, non-pre-B (58); T cell (11); B cell (3); and pre-B cell (28).

Table 1 compares the clinical and laboratory findings for the 14 patients with lymphomatous ALL, with or without an

abnormal chromosome 9p. All seven children with 9p abnormalities had the common ALL phenotype (CALLA⁺, E⁻, sIg⁻, cIg⁻). Only one child (case 7) had both lymphomatous ALL and an abnormal 9p chromosome. The prevalence rate of 9p abnormalities in cases of lymphomatous ALL was not significantly different from that in cases without these features (1 of 8 v 6 of 92, $P = .62$). In addition, lymphomatous features were as likely to be found in patients without 9p abnormalities as in those who had these features (7 of 93 v 1 of 7, $P = .63$).

All children with 9p abnormalities attained complete remission (CR). Only one (case 2) has relapsed in bone marrow (after 9 months of CR), and he is presently in CR 4 years after a bone marrow transplant. The remainder of this group continue in CR for 6 to 36 months (mean 16 months). Three of the eight patients with a lymphomatous presentation never attained CR. Of the 5 children achieving remission, 3 have relapsed in the bone marrow and 1 has relapsed in the central nervous system. The child who had both lymphomatous clinical features and a 9p abnormality (case 7) has been in continuous CR for 27 months.

DISCUSSION

This study demonstrated that abnormalities of the chromosome 9 short arm are nonrandom in childhood ALL, occurring in ~7% of affected children. No significant association between abnormalities of 9p and the T cell immunophenotype or the so-called lymphomatous presentation of ALL was observed. The overall incidence of T cell ALL in our population of children with ALL and satisfactory cytogenetic analyses was 11%, which is similar to that described in large series of children with ALL.¹¹ Furthermore, the 8% incidence of lymphomatous presentation noted in our series is similar to the 10% reported by others.^{12,13} All series reported have noted a poor outlook for children with lymphomatous presentations, as expected, since by definition such patients have more bulk disease and are generally older, factors that have adverse prognostic significance.

Although most of the patients studied by Chilcote and colleagues and by Kowalczyk and Sandberg had 9p deletions, most of our patients had translocations involving 9p. In all three series, the abnormalities centered around the 9p21-22 region. In most cases that involved a translocation, the rearrangement was unbalanced and resulted in the loss of 9p material. In addition, the observation that an abnormal chromosome 9p was involved with different donor chromosomes (8⁵, 10, 12p, 12q, 13, and 21⁴) suggests that deletion or rearrangement of material in the 9p21-22 region may play a role in malignant transformation of the cells.

Our observations regarding the lack of an association between abnormalities of the 9p and lymphomatous and/or T cell ALL are different from those of both Kowalczyk and Sandberg⁴ and Chilcote and colleagues.⁵ This difference could in part relate to the older age distribution of the patients of interest studied in the two comparable study populations with 9p chromosome abnormalities. Four of the 7 patients with the 9p in Chilcote's series were >16 years of age whereas only 2 of 7 of our patients were aged >14 years. The mean age in the series of Kowalczyk and Sandberg was 12.7 years. A known increased incidence of T cell ALL is associated with lymphomatous presentation in adolescent patients.¹⁴ Six out of seven of our children with ALL and the 9p were males, but only one of them was an adolescent (16 years). Thus, the older age distribution in other populations could result in more patients being classified as having lymphomatous leukemia. The selection of hemoglobin (Hb) >10 g/dL as a criteria for lymphomatous ALL may also skew the study population mean age since higher Hb at diagnosis have been associated with older age. A male predominance was also noted in both previous series. Moreover our series of 100 children is larger than that reported by Chilcote and colleagues (41 children) or by Kowalczyk and Sandberg (70), and our immunophenotype distribution is typical for childhood ALL. Our success rate (61%) in obtaining abnormal karyotypes compares favorably to the series by Kowalczyk and Sandberg (60%). The success rate for the series reported by Chilcote and colleagues was not mentioned. Because cytogenetic methodologies used in both comparable studies are similar to our method, we doubt that technical differences account for the difference in our findings.

Recently, other nonrandom translocations have been shown to be specific for certain clinical syndromes of acute or chronic leukemia, or for specific immunophenotypes of ALL.^{2,3,15} Furthermore, some of these translocations occur near genes encoding proteins involved with cell growth.¹⁶ In regard to abnormalities of 9p, the recent observation of Carrera and co-workers¹⁷ that the gene encoding methylthioadenosine phosphorylase, an enzyme important in purine and polyamine metabolism in proliferating lymphocytes, is located on chromosome 9 is of considerable interest. The precise role of each of these chromosomal translocations in the process of malignant transformation is presently being investigated intensely.

Increased Resistance to Membrane Deformation of Shape-Transformed Human Red Blood Cells

By Anne Chabanel, Walter Reinhart, and Shu Chien

The study of shape-transformed human erythrocytes is of hematological interest since several clinical conditions are associated with erythrocyte shape changes. Using the micropipette technique, we examined the rheological behaviors of echinocytes induced by sodium salicylate or ATP depletion and of stomatocytes induced by chlorpromazine. Both the discocyte-echinocyte and discocyte-stomatocyte transformations resulted in an increased resistance

to extension. Sodium salicylate-treated erythrocytes could be returned to normal morphology and normal membrane rheology by addition of chlorpromazine. We conclude that these morphological changes are associated with detrimental effects on the intrinsic membrane deformability of the human erythrocyte.

© 1987 by Grune & Stratton, Inc.

EVIDENCE SHOWS that shape changes of the erythrocyte found in clinical conditions or induced by experimental manipulation are associated with alterations in erythrocyte rheology, which may have detrimental influences on the microcirculation. Abnormal rheologic behavior of non-discocytic, pathologic erythrocytes have been described in several hematological disorders, including sickle cell disease,¹ hereditary elliptocytosis,² hereditary spherocytosis,³ and hereditary stomatocytosis.⁴ Alterations in erythrocyte shape can also be induced by a variety of chemical agents.⁵ Treatment of fresh human erythrocytes with lysolecithin, oleate,^{6,7} 2,4-dinitrophenol,⁷ sodium salicylate (SA),⁸ alkaline medium,⁶ or the Ca^{2+} -ionophore A23187,⁹ as well as ATP depletion,¹⁰ can lead to crenation, ie, formation of echinocytes. On the other hand, erythrocytes become cup-shaped, ie, stomatocytes, following treatment with chlorpromazine¹¹ or local anesthetics,⁸ as well as from cholesterol depletion.^{12,13} These shape changes occur rapidly and are reversible if the distortion is not carried out to the spherocyte stage. These shape transformations might be expected to cause alterations in the rheological properties of erythrocytes through direct modification of the cell geometry (surface area/volume ratio) or through associated alterations of the membrane skeleton. Indeed, several groups have reported that drug-induced shape changes of erythrocytes are accompanied by alterations in the rheological properties of erythrocyte suspensions.^{9,14-18} Reinhart and Chien¹⁸ found that erythrocyte passage through a narrow channel is impaired for stomatocytes and facilitated for echinocytes; these changes in rheological behavior were explained by altered surface area/volume relationship, as the isovolumic shape transformations were accompanied by a loss of surface area in stomatocytes and a gain of surface area in echinocytes. Because microsieving measurements cannot clearly dissociate the contributions of the various determinants of cell deformability (cell geometry, internal cell viscosity, and membrane mechanical properties), the present experiments were performed to investigate directly the membrane mechanical properties of shape-transformed erythrocytes by using the micropipette aspiration technique. Indeed, the micropipette test is suited to the study of membrane mechanical properties since it has been shown that the viscous dissipation inside the RBC in a small deformation during aspiration into a micropipette is negligible under isotonic conditions.¹⁹

MATERIALS AND METHODS

RBC suspensions. Blood was drawn from healthy human volunteers into heparinized vacutainer tubes. The blood was centrifuged at $1,500 \times g$ for 10 minutes, and the plasma and the buffy coat were removed. The erythrocytes were washed three times in a standard buffer used throughout this study; this buffer contained 0.85 g/dL of NaCl, 0.25 g/dL of bovine serum albumin (BSA) and 0.1 g/dL of EDTA; its pH was adjusted to 7.4 with 0.1 N Tris. The washed erythrocytes were resuspended in the buffer at a hematocrit of 10%.

Stomatocytes were produced in vitro with chlorpromazine hydrochloride (CP), and echinocytes were produced with SA. A calculated volume of the suspending medium of the 10% erythrocyte suspension was replaced by an equal volume of a stock solution of CP (1.5 mmol/L) or SA (160 mmol/L). The suspensions were incubated for 20 minutes at room temperature and then used for measurements. ATP-depleted cells were obtained by incubation of whole blood under sterile conditions for 24 hours at 37 °C. The depleted erythrocytes were resuspended in the autologous plasma to a hematocrit of 10%.

Micropipette technique. The micropipette technique has been described elsewhere.²⁰ Micropipettes with an internal radius (R_p) of 0.45 to 0.70 μm were prepared with a micropipette puller (Narishige Scientific Instrument Laboratory, Tokyo). The micropipette was filled with the buffer solution and mounted on a micromanipulator (Narishige). The wide end of the micropipette was connected to a pressure-regulating system, which consisted of two reservoir bottles and a damping chamber. By adjustment of the relative heights of the reservoir bottles with a micrometer device, desired pressure levels were preset and then imposed on the micropipette by turning a stopcock. The applied pressure was measured with a transducer (model 23 BC, Statham Instrument, Oxnard, CA) and recorded with an amplifier-recorder system (Gould, Cleveland). A suspension

of erythrocytes at a hematocrit level of $\sim 0.05\%$ was placed in a small round chamber located on the stage of a Nikon inverted microscope (Ehrenreich Photo-Optical, Garden City, NY). The erythrocytes were viewed with the use of a $100\times$ objective and a $20\times$ eye piece. The image was recorded with a video camera and tape recorder system (Panasonic, Division of Matsushita Electric of America, Franklin Park, IL). The micropipette tip was manipulated for positioning at the surface of the erythrocyte membrane. A small portion of the erythrocyte was aspirated by a preset negative pressure for 20 seconds. The length of the aspirated tongue and the radius of the pipette were measured on a television screen. The membrane extensional rigidity, which reflects the steady-state resistance to deformation, was calculated from the relationship between the stress applied, $(\Delta P)R_p$, and the strain induced, D_{pm}/R_p ,²⁰ where ΔP is the applied negative pressure, R_p is the internal radius of the micropipette, and D_{pm} is the maximum length of the aspirated portion within the micropipette. When the aspiration pressure was removed, the deformed erythrocyte segment in the micropipette decreased in length with time, and the cell recovered its original shape. All measurements were made at room temperature (21 to 24°C). For each experiment, the same micropipette was used to test shape-transformed RBCs and control RBCs. Statistical analysis of the data was performed by comparison of the slope of the linear regression using a paired Student's *t* test²¹ or by analysis of variance followed by the Newman-Keuls test.²²

Scanning electron microscopy. RBC specimens were fixed in 1.0% glutaraldehyde in cacodylate buffer. After two cacodylate buffer rinses, the specimens were processed through an ethanol dehydration series from 30% to 100% ethanol. The cells were resuspended in 100% ethanol and gently dropped onto a glass coverslip that had been cleaned with ethanol. After being air-dried, the coverslip with cells was glued onto aluminum stubs (JEOL USA, Electron Optics Division, Peabody, MA) with silver conductive paint. The stubs with samples were coated with gold-palladium in a sputterer (Hummer I; Technics, Alexandria, VA), and the specimens were viewed and photographed in a scanning electron microscope (JEOL 35; JEOL USA) at 25 kV .

RESULTS

Bessis' nomenclature²³ was used to classify erythrocytes according to their shape. Thus, a discocyte is a normal biconcave RBC with a smooth contour, echinocyte I is a flat erythrocyte with an irregular contour, echinocyte II is a flat erythrocyte with one or several spicules, and echinocyte III is an ovoid or spherical cell with numerous spicules evenly distributed over its surface. Stomatocytes are bowl-shaped cells with a single concavity (stoma); the concavity is large and shallow in stomatocytes I, deep and narrow like a token-slit in stomatocytes II, and deep and folded in stomatocytes III. Spherostomatocytes have a smaller diameter and small irregular invaginations. The morphology corresponding to this classification is illustrated in Fig 1.

Erythrocytes incubated with 25 or $100\text{ }\mu\text{mol/L}$ of CP produced stomatocytes I through III. Incubation of erythrocytes with 20 mmol/L of SA or depletion of their ATP content for 24 hours at 37°C produced echinocytes over the whole range from echinocytes I to spheroechinocytes. The micropipette test was carried out on every type of erythrocyte. Their mechanical behavior can be compared by plotting the steady-state deformation (D_{pm}) normalized for the pipette radius (R_p) against the stress parameter $(\Delta P)R_p$. When the aspiration was performed at a spicule site, the length of the protrusion inside the pipette prior to the application of

Fig 1. Scanning electron micrographs of control discocytes (D); echinocytes type I (EI), type II (EII), and type III (EIII); stomatocytes type I (SI), type II (SII), and type III (SIII); and spherostomatocytes (SphS). Bar = $2\text{ }\mu\text{m}$.

aspiration pressure was subtracted from the length of the tongue induced by the negative pressure to give the steady-state deformation (D_{pm}). Figure 2 shows the results for the echinocytes. The slope (*K*) of the stress-strain relationship was obtained by linear regression analysis of the data on D_{pm}/R_p v $(\Delta P)R_p$. The extensional rigidity was calculated as $1/0.245\text{ K}$; the value of 0.245 was based on the model described in ref. 20. Because the geometry at the point of aspiration is not an infinite plane, in shape-transformed RBCs we could not readily use the mathematical model to derive values for the intrinsic membrane elastic modulus; ie, due to the geometry of the cell, the micropipette test cannot distinguish between an effect on the membrane elastic modulus itself and a consequence in overall cell geometry that might generate local membrane tensions. By analogy with the work of Evans and colleagues²⁴ and Nash and co-workers,²⁵ who studied sickle cells (another type of abnormally shaped RBC) by micropipette test, we used values for the extensional rigidity to allow simple comparison of the resistance to deformation of shape-transformed RBCs and control discocytes. Extensional rigidity significantly and progressively increased with the degree of echinocytosis (Table I).

Fig 2. Strain (D_{pm}/R_p)–stress ($\Delta P \times R_p$) relationship for discocytes (C, ●); and echinocytes type I (EI, □), type II (EII, ▲), and type III (EIII, ○). Lines represent linear regressions computed from n data pairs for each group ($n > 55$). Data points were grouped according to $\Delta P \times R_p$, with mean $\pm$ SEM shown for each group.

There was no significant difference in membrane rheological behavior between the echinocytes induced by SA or ATP depletion (Table 1). Less stress was required to deform an echinocyte between the spicules than at a spicule site (Table 1). The intercept on the strain axis (ordinate) at zero stress decreased with the degree of echinocytosis (Fig 2).

Because it was often difficult under light microscopy to determine the degree of stomatocytosis, stomatocytes I through III were grouped together in the analysis. Figure 3 compares the elastic behavior of stomatocytes I through III and spherostomatocytes induced by different concentrations of CP to that of control discocytes. The value of extensional rigidity for the control cells in the stomatocyte set of experiments (Table 2) was different from that in the echinocyte set of experiments (Table 1). These two sets of experiments were performed on different days with different blood

Fig 3. Strain (D_{pm}/R_p)–stress ($\Delta P \times R_p$) relationship for discocytes (C, ●), stomatocytes types I through III (SI through III, Δ), and spherostomatocytes (SphS, ○). Lines represent linear regressions computed from n data pairs for each group ($n > 39$). Data points were grouped according to $\Delta P \times R_p$, with mean $\pm$ SEM shown for each group.

donors. The overall range of values for extensional rigidity for the control cells was 3×10^{-3} to 12×10^{-3} dynes/cm. The stress needed to obtain a comparable D_{pm}/R_p was approximately three times greater for stomatocytes I through III than for discocytes, and it was ~ 30 times greater for spherostomatocytes than for discocytes (Fig 3). Values for the extensional rigidity are shown in Table 2.

These data show that both the discocyte–echinocyte and the discocyte–stomatocyte transformations resulted in increases of membrane extensional rigidity. The membrane rheological behavior of erythrocytes that had been transformed to echinocytes by SA (20 mmol/L) and subsequently returned to a discocytic shape by addition of CP (2.5 μ mol/L) was also studied (Fig 4). With the insertion of both of these drugs in the erythrocyte membrane, the rheological behavior of the membrane returned to normal as the discocytic shape was recovered.

DISCUSSION

This study demonstrates that membrane deformability is decreased in shape-transformed erythrocytes (both echinocytes and stomatocytes) as assessed by the micropipette technique. Although no data exist on stomatocytes, several groups have studied echinocytes. Leblond,⁶ using a micropipette with a diameter of 1.5 μ m, found a decreased membrane deformability in echinocytes induced by oleate, high pH, aged plasma, and ATP depletion, which is in agreement with our results. Baker,²⁶ measuring erythrocyte deformabil-

Spherostomatocytes	16	163.9 ± 20.4	0.01

*Values are mean $\pm$ SEM.

†P values are based on an analysis of variance followed by a Newman-Keuls test for the different types of stomatocytes as compared with discocytes.²²

Fig 4. Normalized membrane deformation (D_{pm}/R_p) at two different deforming stresses ($\Delta P \times R_p$) for control discocytes (C), echinocytes produced by 20 mmol/L of salicylate (SA), and after biconcave shape recovery with the addition of 2.5 μ mol/L chlorpromazine (SA + CP). The vertical bars represent SEM.

ity by aspiration in Nuclepore filters with 0.6- μ m pores, found that ATP-depleted erythrocytes were 16% less deformable than fresh cells. Meiselman and co-workers,²⁷ however, using the micropipette test, reported that the decreased membrane deformability of ATP-depleted erythrocytes was not statistically significant. In these two last studies, the authors did not report any correction for the length of the spicule at rest inside the micropipette or the filter pore. The absence of such correction would lead to an overestimation of the length of the pressure-induced deformations and an underestimation of the elastic modulus for the echinocytes; this may explain the lesser effects seen in their results as compared with the present data. When we subtracted the mean spicule length from the pressure-induced pseudopod length, using Baker's technique with Nuclepore filters,²⁶ the membrane deformability of echinocytes also decreased (W. Reinhart, A. Chabanel, and S. Chien, unpublished observations, April 1985) to an extent similar to that found by the micropipette technique in the present study. Leblond⁶ reported that ATP-depleted cells were much more rigid than drug-crenated cells. Although we also observed a greater rigidity of the ATP-depleted echinocytes as compared with the echinocytes induced by SA, the difference was not statistically significant. Determining the deformability of resealed human erythrocyte ghosts in the ektacytometer, Shrier²⁸ found that the echinocytic ghosts were more deformable than the discocytic ghosts, whether the ghosts were prepared from discocytic or echinocytic erythrocytes. He concluded that acquisition of the discocytic shape in ghosts is accompanied by an increase in membrane rigidity. The reason for the discrepancy between his results and ours is not clear. One possible explanation is that the influence of the cellular geometry is dominant over that of membrane deformability in measurements performed with the ektacytometer. In that case, Schrier's results are consistent with the results of Reinhart and Chien¹⁸ on filtration through narrow pores, in which cell geometry is a major determinant of filterability; they found that echinocyte passage through narrow pores is facilitated rather than retarded

as compared with that of discocytes. Meiselman and co-workers reported that the suspension viscosity of echinocytes induced isovolumically by 2,4-dinitrophenol, 2,4,6-trinitrophenol, or SA¹⁷ and by ATP depletion¹⁵ was higher than that of normal cell suspensions at low shear rates but nearly normal at high shear rates. Because it was believed that change in cellular deformability would be reflected by a change in suspension viscosity at high shear rate, they concluded that altered morphology, rather than erythrocyte membrane deformability, was the cause of the rheologic changes. Minor or moderate changes in membrane rheology, however, may be detected by suspension viscosity measurements only at low or medium shear rates.²⁹ Considered thus the viscometric results obtained by Meiselman and Baker^{15,17} are in accord with our micropipette measurements in showing that shape transformation of erythrocytes results in an increased resistance to membrane extension.

This increase in resistance to membrane extension could be the consequence of (a) changes in the molecular organization of the membrane due to drug insertion or ATP depletion and/or (b) changes in the physical properties due to modification of the cell shape. Several groups have reported changes of the protein-lipid interface induced by CP,³⁰⁻³³ suggesting that interaction between the drugs (CP or SA) and the erythrocyte membrane constituents may lead to the increase in membrane rigidity. When both drugs were incorporated to cause the recovery of normal biconcave cell shape, we found that membrane deformability also returned to normal. This is in agreement with the results of Meiselman,¹⁷ who showed that both the morphology and rheology of 2,4-dinitrophenol-treated erythrocytes could be returned toward those of fresh control erythrocytes by addition of the antagonist chlorpromazine. Although we cannot rule out the possibility that when both drugs are added they have mutually compensating effects in their interaction with the membrane constituents, our data seem to support the concept that erythrocyte morphology per se has an important relation to the membrane mechanical properties. Leblond⁶ has proposed that the increased resistance to deformation observed in echinocytes may reflect the presence of new forces whose action is to produce foldings on the cell surface and hence to resist extension into the micropipette in response to pressure aspiration. We found that the intercept on the strain axis at zero stress decreased with the degree of echinocytosis (Fig 2), indicating that increasing stresses are required to reach a given extensional deformation. This might reflect an increase in the resting membrane tension as proposed by Leblond.⁶ Although we do not know if the spicule sites are predetermined, the present data show that the formation of spicules on an erythrocyte results in regional variations of physical properties on the membrane.

In conclusion, the present data demonstrate that changes in local membrane properties associated with overall erythrocyte shape transformation affect its membrane deformability. The decrease in erythrocyte membrane deformability following shape transformation could be of importance in the microcirculation when the erythrocyte must deform to negotiate its entrance into narrow capillaries.

High-Dose Cytosine Arabinoside and Mitoxantrone: A Highly Effective Regimen in Refractory Acute Myeloid Leukemia

By W. Hiddemann, H. Kreutzmann, K. Straif, W.D. Ludwig, R. Mertelsmann, R. Donhuijsen-Ant, E. Lengfelder, Z. Arlin, and T. Büchner

In a clinical phase I/II study, high-dose cytosine arabinoside and mitoxantrone (HAM) were given in combination to 40 patients with refractory acute myeloid leukemia. All patients had received a 9-day combination of thioguanine, Ara-C, and daunorubicin (TAD-9) as standardized first-line treatment. Refractoriness was defined as (a) nonresponse against two TAD-9 induction cycles, (b) early relapse within the first 6 months on monthly maintenance or after TAD-9 consolidation, (c) relapse after 6 months with nonresponse against one additional TAD-9 cycle, and (d) second and subsequent relapses after successful TAD-9 therapy at the preceding relapse. Therapy consisted of HD-Ara-C 3 g/m² every 12 hours on days 1 through 4; mitoxantrone was started at 12 mg/m²/day on days 3, 4, and 5 and was escalated to 4 and 5 doses of 10 mg/m²/day on days 2 through 5 and 2 through 6. Of the 40 patients, 21 achieved a complete remission (53%), 1 patient had a

partial remission, and 5 patients were nonresponders. Thirteen patients died in aplasia due to infections (n = 11), pericardial effusion, or acute cardiomyopathy. Nonhematologic side effects consisted predominantly of nausea and vomiting, mucositis, and diarrhea. Central nervous system (CNS) symptoms were observed during six treatment courses. Recovery of blood counts occurred at a median of 27 days from the onset of treatment; the median time to complete remission was 36 days. Two of the 21 responders underwent successful bone marrow transplantations. The median remission duration for the remaining 19 patients is 4.5 months, and the median survival time is 9 months. These data emphasize that HAM has high antileukemic activity in refractory AML and strongly suggest starting the combination at earlier stages in AML therapy.

© 1987 by Grune & Stratton, Inc.

DESPITE INTENSIVE induction therapy and subsequent myelosuppressive treatment in remission, most patients with acute myeloid leukemia (AML) still relapse with their disease and ultimately die of drug-resistant leukemia. High secondary remission rates and even prolonged survival have recently been reported, however, with administration of high-dose cytosine arabinoside (HD-Ara-C) alone or in combination with anthracyclines, asparaginase, or m-AMSA.¹⁻⁶ Patients with leukemias refractory to conventional-dose Ara-C especially benefitted from the addition of anthracyclines.⁵ These data are in accordance with previous cell kinetic studies revealing a conditioning effect of Ara-C for the subsequent administration of daunorubicin or doxorubicin.⁷⁻¹⁰ They are further supported by recent experimental results indicating a time-dependent synergistic effect of high-dose cytosine arabinoside (HD-Ara-C) and mitoxantrone.¹¹

These findings and the significant antileukemic activity of mitoxantrone as a single agent¹²⁻¹⁶ as well as its low cardiac toxicity¹⁷⁻²⁰ prompted us to initiate a phase I/II study of HD-Ara-C and mitoxantrone (HAM) in patients with refractory AML. All patients were recruited from the multi-

center German AML Cooperative Group trial^{21,22} and had therefore received a standardized first-line treatment with a 9-day combination of thioguanine, Ara-C, and daunorubicin (TAD-9).

HD-Ara-C was given every 12 hours at a dose of 3 g/m² by a 3-hour infusion to compensate for its rapid metabolic clearance and because steady-state plasma levels are not achieved before ~45 minutes.²³ The 3-hour infusion is also thought to reduce cerebellar toxicity associated with short-term administration.^{24,25} The number of HD-Ara-C infusions was restricted to 8 to avoid the sustained nonhematologic side effects reported for repetitive doses beyond 8 to 10.^{24,25} To take advantage of the previously mentioned conditioning effect of Ara-C, mitoxantrone was started on day 3 at 12 mg/m²/day and was repeated on days 4 and 5. In subsequent patients the total dose was escalated to 10 mg/m²/day for 5 days, which is in the range of the most effective single-agent regimens.¹²⁻¹⁶

Patients were eligible for the HAM regimen only if they were refractory to prior treatment.²⁶ Hence, they had either failed or two TAD-9 courses for induction treatment, had relapsed within the first 6 months on monthly maintenance including conventional dose Ara-C or after TAD-9 consolidation, were nonresponders to an additional TAD-9 course in later occurring first relapses, or had second or subsequent recurrences after successful TAD-9 therapy at the preceding relapse.

MATERIALS AND METHODS

Between January 1985 and March 1986, 40 patients entered the study from seven centers in Germany. Their ages ranged from 18 to 66 years (median 45 years). All patients had received one to two courses of the TAD-9 regimen for induction, consisting of thioguanine 200 mg/m²/day on days 3 to 9, Ara-C 100 mg/m²/day by continuous infusion on days 1 and 2 followed by short-term infusions of Ara-C 100 mg/m² every 12 hours on days 3 to 8, and daunorubicin 60 mg/m²/day on days 3 to 5 (TAD-9). For postinduction treatment, patients received TAD-9 consolidation and/or monthly maintenance therapy with subcutaneous Ara-C alternately combined with daunorubicin, thioguanine, or cyclophosphamide.^{21,22}

Besides Ara-C at conventional dosage, all patients were therefore exposed to daunorubicin at cumulative doses between 180 and 990 mg/m² (median 450 mg/m²). All patients were refractory to conventional therapy as defined earlier (Table 1).

In three cases, AML was preceded by myelodysplastic syndrome. Two additional patients had secondary leukemias after radiation and chemotherapy for breast cancer and malignant seminoma, respectively. Four patients with early relapses had central nervous system (CNS) involvement.

Prior to therapy all patients gave informed consent after having been advised about the purpose and investigational nature of the study as well as of potential risks.

Therapy consisted of HD-Ara-C 3 g/m² every 12 hours by a 3-hour infusion on days 1 through 4. Mitoxantrone was started at 12 mg/m²/day as a 30-minute infusion on days 3, 4, and 5 and was escalated in subsequent cases to four and five doses of 10 mg/m²/day on days 2 through 5 and 2 through 6, respectively (Fig 1). For the prophylaxis of HD-Ara-C-induced photophobia and conjunctivitis, all patients received glucocorticoid eye drops every 6 hours starting before the first dose and continuing for 24 hours after the last dose of HD-Ara-C.

Toxicity was quantitated according to the World Health Organization (WHO) grading system.²⁷ For the most frequently encountered side effects, toxicity grades 3 and 4 are thereby defined as follows: nausea and vomiting—vomiting requiring therapy (grade 3); intractable vomiting (grade 4); diarrhea—repetitive diarrhea for >2 days requiring therapy (grade 3); severe hemorrhagic diarrhea with dehydration (grade 4); mucositis—ulcers requiring liquid diet only (grade 3); alimentation impossible, parenteral nutrition required (grade 4); and hepatic—increase in liver enzymes or bilirubin to 5 to 10 times the normal values (grade 3) or to >10 times the normal values (grade 4). In addition, cardiac function was monitored in all patients by echocardiographic measurement of left ventricular shortening fraction prior to therapy and at 4- to 6-week intervals thereafter.

Evaluation of antileukemic efficacy was based on CALGB criteria.^{28,29} Complete remission was defined by the disappearance of leukemic blasts from the bone marrow and blood as well as from possible extramedullary sites, including the cerebral fluid, and the normalization of peripheral blood counts to thrombocytes >100,000/ μ L and granulocytes >1,500/ μ L. The duration of critical cytopenia was evaluated by the time for granulocyte recovery to

Fig 1. Schema of the high-dose cytosine arabinoside (HD-Ara-C)/mitoxantrone (HAM) protocol indicating the uniform dosage of HD-Ara-C 3 g/m² every 12 hours on days 1 through 4 and a dose escalation for mitoxantrone from 12 mg/m²/day on days 3 through 5 to four and five doses of 10 mg/m²/day on days 2 through 5 and 2 through 6.

>500/ μ L and thrombocytes to >20,000/ μ L from the onset of treatment.

RESULTS

Thirty-seven of the 40 patients were treated with one course of HAM, and three patients received a second cycle of the same regimen, accounting for 43 treatment courses. Eight cycles were carried out at the starting dose of mitoxantrone of 12 mg/m²/day $\times$ 3. In 16 and 19 courses, respectively, mitoxantrone was escalated to 4 and 5 doses of 10 mg/m²/day.

Nonhematologic toxicity. A summary of the nonhematologic side effects is given in Table 2. Nausea, vomiting, diarrhea, and mucositis were the most frequent side effects, occurring in 39 (91%), 35 (81%), and 30 (69%) of the 43 treatment courses. Severe side effects with toxicity grades of 3 and 4 according to WHO criteria were seen only in 9 (21%), 9 (21%), and 7 (16%) patients. Apart from more pronounced mucositis at the highest dose of mitoxantrone,

†Includes one death due to acute cardiomyopathy.

toxicity was not different among the three applied dose escalations.

Two fatal cardiac events occurred at the lowest dose of mitoxantrone. One 31-year-old woman patient who had received 360 mg/m² of daunorubicin during prior therapy died of sudden cardiac failure 12 hours after the first dose of mitoxantrone. Autopsy revealed an acute cardiomyopathy. The other patient succumbed to a massive pericardiac effusion because of leukemic infiltration. Atrial flutter was observed in a third patient with preexisting cardiac arrhythmias during the initial HD-Ara-C infusion but was easily controlled by antiarrhythmic medication and did not cause cessation of treatment. Minor arrhythmias not requiring therapy occurred in two patients; in three additional patients, a reduction of left ventricular shortening fraction was revealed 3 to 8 weeks after HAM without any clinical signs of cardiac insufficiency.

In addition to two patients with transient dysdiadochokinesia, four patients aged 54, 59, 60, and 64 years had more severe CNS symptoms consisting of dysarthria, ataxia, balance disturbances, and somnolence. The clinical symptoms were completely reversible within 2 to 3 weeks in two patients; the other two died of septicemia during bone marrow aplasia.

Hematologic effects and antileukemic efficacy. Twenty-one of the 40 patients (53%) achieved complete remission (CR), 19 of them after one HAM course and 2 of them after two HAM courses. One additional patient obtained a partial remission (PR) with a normalization of peripheral blood counts but a residual leukemic cell population in the bone marrow of 15% blasts.

In five patients (13%), the leukemic blasts persisted or recovered after bone marrow aplasia; they were therefore considered nonresponders.

Three of the four patients with initial CNS involvement had no evidence of residual leukemic blasts in the cerebral fluid 1 week after completion of HAM without any intrathecal therapy and went into CR; the fourth patient died in aplasia due to an overwhelming infection.

Thirty-three of the 40 patients developed fever during bone marrow aplasia, and 11 (28%) died of infections between days 7 and 36 (median day 14) from the onset of therapy. Posttreatment bone marrow smears were available in nine cases and revealed residual leukemic blasts in only one patient. The two additional deaths caused by acute cardiomyopathy and pericardiac effusion occurred on days 2 and 7, respectively.

Analysis of response in relation to the previously defined entry criteria (Table 3) revealed similarly high CR rates in patients with early relapses (9 of 13) in TAD-9-resistant late relapses (3 of 8) and in patients with second and subsequent leukemic recurrences (8 of 9). Of the ten primary nonresponders only one patient achieved a CR. This group includes, however, two cases with antecedent myelodysplastic syndromes, two with additional ineffective salvage treatment by COAP or Aclacinomycin A and VP 16 and the patient who died of a pericardiac effusion (Table 4).

In patients achieving a CR ($n = 21$) or PR ($n = 1$), the median recovery time of granulocyte counts to $>500/\mu\text{L}$ and thrombocyte counts to $>20,000/\mu\text{L}$ was 27 days (range 21 to 150 days) from the start of treatment. The median time to complete remission was 36 days (range 24 to 190 days). No cases of prolonged aplasia occurred except for one patient at third relapse who had been exposed to previous multiple intensive regimens and who fulfilled CR criteria after 190 days.

Of the 21 CR patients, two underwent allogeneic bone marrow transplantations after 1⁺ and 2⁺ months of CR and both are presently in continuous CR at 16⁺ and 20⁺ months. Four patients are in ongoing remission at 1⁺ to 7⁺ months, whereas 15 relapsed after 1 to 8 months. The median remission duration is 4.5 months. Of the 15 relapsed patients, 8 were successfully reinduced with a modified HAM regimen, and 7 were refractory or died. The overall survival

times are 3 months for all patients and 9 months for the 21 CR cases.

DISCUSSION

In refractory and relapsed acute leukemias, clinical phase I/II studies are performed not only as salvage therapy for patients with advanced disease but also as a search for new agents or drug combinations with antileukemic activity that will broaden the spectrum of leukemia treatment and may subsequently be incorporated into first-line therapy. The clinical evaluation of these trials and the interstudy comparison of treatment results are substantially hampered, however, by the great heterogeneity of patients entered on phase I/II protocols. In addition to various forms of first-line therapy, differences in the duration of the preceding remission and in the definition of patient eligibility may cause divergent results and must be considered.^{30,31}

The present phase I/II study combining HD-Ara-C and mitoxantrone (HAM) was based on the first-line multicenter trial of the German AML Cooperative Group²² and was thus applied under standardized conditions for the initial treatment by TAD-9, producing a 62% CR rate in 844 adults of all ages. Furthermore, rigid criteria for the definition of refractoriness against first-line therapy were applied according to the analysis of relapse pattern and response to reinduction attempts with the TAD-9 regimen initially used. This evaluation indicated a substantially inferior remission rate in patients relapsing within the first 6 months (19% CR) as compared with later relapses (45% CR). TAD-9 was also ineffective in cases with second and subsequent leukemic recurrences producing 21% CR. Hence, patients were eligible for HAM only if they had either failed on induction therapy, relapsed within 6 months during intensive monthly maintenance treatment or after a full-dose induction-type consolidation, were nonresponders to a reinduction attempt with TAD-9 at later recurrences, or were at second or subsequent relapses. Under these prerequisites, the response rate of 53% CR demonstrates a substantial antileukemic activity of HAM in refractory AML.

Willemze and colleagues¹ treated 14 similarly selected patients by a six-day course of HD-Ara-C alone and obtained 6 CR and 1 additional hematologic CR with persistent extramedullary leukemia; however, they reported considerable pulmonary toxicity in three patients. This side effect was not observed by Herzig and co-workers at the same dose level,² with which 12 of 19 evaluable patients with AML achieved a CR. Five patients dying during the first 3 weeks were considered invaluable, and the responses were not classified according to prior therapy or relapse status. The overall study comprised 36 patients who had received different types of primary treatment and of whom only 14 were considered refractory against conventional-dose Ara-C. In a recent report by the same group,³ 3 of 15 patients with AML resistant to conventional-dose Ara-C responded to 12 doses of HD-Ara-C whereas addition of an anthracycline produced 15 CR in 27 similarly selected AML patients. Remission rates for combinations of HD-Ara-C with *m*-AMSA range from 33% to 70%.^{4,6,32,33} These trials are hardly comparable, however, because of different drug schedules and doses. In addition, information about the prior therapy and eligibility

criteria including the resistance to conventional-dose Ara-C are not available. The latter data are given for two recent trials with sequential HD-Ara-C and asparaginase in children and adults^{3,34} achieving CR in 42% to 68% of cases. The earlier study³ also included patients without prior Ara-C treatment; in both trials, patients with late relapses were eligible if they were still receiving maintenance therapy.

These data emphasize the limits of interstudy comparison but strongly suggest that HAM is at least equivalent or possibly even superior to other HD-Ara-C regimens as well as to the combination of mitoxantrone and VP-16³⁵ in truly refractory AML. Preliminary results of a recent study using HD-Ara-C and mitoxantrone at a different dosage and timing confirm the high overall remission rate, although 4 of 10 patients needed more than one treatment cycle to obtain a CR.³⁶

Analysis of treatment response according to the previously defined entry criteria revealed high remission rates in patients with early relapses and TAD-9-resistant late relapses as well as in second and subsequent recurrences, but only one CR in ten patients with primary resistance against two TAD-9 induction cycles. Although additional factors such as antecedent myelodysplastic syndromes and further salvage therapy must be taken into account in four patients, these results seem to imply that primary refractoriness against two TAD-9 cycles might not be overcome by HAM. Due to the relatively small number of truly evaluable primarily resistant patients, this conclusion must be considered preliminary and deserves confirmation by additional cases.

Despite intensive prior therapy and exposure to a median cumulative dose of 450 mg/m² of daunorubicin (range 180 to 990 mg/m²), the toxicity of HAM was acceptable at all dose levels. The only cardiac death that was obviously related to therapy consisted of an acute cardiomyopathy in a 31-year-old patient without a prior history of cardiac disorder who had previously received 360 mg/m² of daunorubicin. Two cases of minor arrhythmias and one incidence of atrial flutter were observed during the first infusion of HD-Ara-C, as has been described by others,¹ and were easily controlled by antiarrhythmic medication. A second cardiac death was due to a massive pericardiac effusion because of leukemic infiltration and was not related to treatment toxicity. Three other patients developed a reduction of left ventricular shortening fraction 3 to 8 weeks after HAM without any clinical signs of cardiac insufficiency. The incidence and severity of CNS toxicity are comparable with that of other HD-Ara-C regimens,^{4,5,34} as are the hematologic effects of HAM. Blood counts recovered to granulocytes $\geq 500/\mu\text{L}$ and thrombocytes $>20,000/\mu\text{L}$ at a median of 27 days after the onset of therapy, and the median time to complete remission was 36 days. Corresponding recovery times are reported for combinations of HD-Ara-C with anthracyclines, *m*-AMSA, and asparaginase.^{3,5,6,34}

The overall early death rate of 33%, which certainly exceeds the results of some other HD-Ara-C trials, must be judged in consideration of the rigid eligibility criteria for the present study. Patients with primarily refractory AML or nonresponse to TAD-9 at late occurring relapses are in continuous hypoplasia or aplasia for 4 to 8 weeks before

entering the HAM protocol. Therefore, they carry a high risk of acquiring severe infections, the major cause of death in 11 of the 13 cases. Ten of the 13 early deaths were observed in patients of the two mentioned subgroups. In this context, the low rate of 12% HAM-resistant leukemias must be emphasized as well; the rate compares favorably with those of other

HD-Ara-C or mitoxantrone combinations.^{6,34,35} Hence, despite selection of heavily pretreated patients with advanced disease and poor prognosis, HAM produced an encouraging high overall response rate, which strongly suggests incorporating the two-drug combination at earlier stages of AML treatment.

Characterization of Glucocorticoid Receptors and Glucocorticoid Receptor mRNA in Human Leukemia Cells: Stabilization of the Receptor by Diisopropylfluorophosphate

By Clark W. Distelhorst and Roger Miesfeld

We have shown that cytosol samples from human leukemia cells frequently contain glucocorticoid receptor fragments that have a mol wt (M_r) of $\sim 52,000$. In the present study we demonstrate that the $M_r \sim 52,000$ -receptor fragments are derived from intact glucocorticoid receptors ($M_r \sim 97,000$) by the action of a serine protease. $M_r \sim 52,000$ -receptor fragments were present in cytosol from 24 of 52 leukemia cell samples. Only normal size glucocorticoid receptors were present in cytosol samples if diisopropylfluorophosphate (DFP), a potent inhibitor of serine proteases, was added to the hypotonic buffer used for cytosol preparation. Receptor proteolysis was not inhibited by hydrolyzed DFP, benzamidine, phenylmethylsulfonylfluoride, aprotinin, iodoacetamide, or mercuric chloride. The leukemia cell protease digests the receptor at a different site than chymotrypsin, which digests the intact receptor to produce a

$M_r \sim 40,000$ receptor fragment. Receptor messenger RNA (mRNA) in S49 mouse lymphoma cells and in human leukemia cells was analyzed by Northern hybridization with a cDNA for the normal glucocorticoid receptor. Mutant S49 mouse lymphoma cells that have abnormally small glucocorticoid receptors ($M_r \sim 48,000$) make a 5.0-kilobase receptor transcript in addition to the normal size 6.5-kilobase receptor transcript. A normal size receptor transcript of 6.5 kilobases was present in all of the human leukemia cells whether or not $M_r \sim 52,000$ -receptor fragments were present. Therefore, abnormalities of glucocorticoid receptor mRNA, which may give rise to the synthesis of foreshortened receptors in certain mutant mouse lymphoma cells, are apparently absent from human leukemia cells.

THE EFFECTS of glucocorticosteroids on cells are mediated through receptors that bind the steroid hormone molecule to form a steroid-receptor complex.¹ The steroid-receptor complex then interacts with specific regions in the genome to regulate gene transcription.² Glucocorticoids kill leukemia and lymphoma cells and, therefore, are an important therapeutic modality for leukemias and lymphomas. Although the exact mechanism of cell killing by glucocorticoids is unknown, studies of glucocorticoid-sensitive and glucocorticoid-resistant mouse lymphoma cell lines have demonstrated that the cell killing process is mediated through glucocorticoid receptors and that a variety of receptor defects can result in glucocorticoid resistance.³

Because of the importance of glucocorticoids in the therapy of human leukemias and lymphomas, there is considerable interest in the structural and functional properties of glucocorticoid receptors in human leukemia and lymphoma cells. Recent studies have found that glucocorticoid receptors

in many human leukemia cells are abnormal in terms of their physical properties and their ability to bind to DNA cellulose or diethylaminoethyl (DEAE) cellulose.^{4,5} Glucocorticoid receptors in cytosol from human leukemia cells are subject to digestion by endogenous proteases.⁵⁻⁸ Thus it has been suggested that previously described abnormalities of glucocorticoid receptor function could be due to the presence of receptor fragments in leukemia cell cytosol and that glucocorticoid receptors in most, if not all, human leukemia cells are normal in size prior to digestion by endogenous proteases.^{5,7}

The mechanisms of glucocorticoid receptor degradation in cytosol from both normal cells and leukemia cells is currently being studied by several groups of investigators. Sherman et al⁹ demonstrated proteolytic degradation of the intact glucocorticoid receptor in rat liver and kidney cytosol to the meroreceptor, which is the smallest receptor fragment ($M_r \sim 20,000$ to $25,000$) that retains the steroid binding site. The extent of receptor degradation appeared to correlate with the activity of "lysine-specific" endopeptidases.⁹ Both Sherman et al⁷ and Holbrook et al⁵ demonstrated the presence of meroreceptors in cytosol from human leukemia cells. The specific protease(s) responsible for receptor degradation in human leukemia cell cytosol have not been identified. However, Sherman et al⁷ found high activities of peptidases of various specificities in human leukemia cell cytosols and showed that a lysine-specific endopeptidase isolated from rat kidney cytosol is capable of converting the glucocorticoid receptor in chronic lymphocytic leukemia cells to a meroreceptor.¹⁰ Holbrook et al⁸ found that glucocorticoid receptors from acute nonlymphocytic leukemia cells could be stabilized by a factor from chronic lymphocytic leukemia cells. Therefore receptor degradation to the meroreceptor form is influenced not only by the presence or absence of receptor degrading proteases but also by the level of factors in leukemia cell cytosol that inhibit receptor proteolysis.⁸

We recently found that cytosol from human leukemia cells frequently contains a $M_r \sim 52,000$ -receptor fragment.¹¹ The

$M_r \sim 52,000$ -receptor fragment was not unique to a particular type of leukemia and was present in samples from previously untreated and previously treated patients.¹¹ This receptor fragment is considerably larger than the meroreceptor fragment described previously by others (see above) and corresponds closely in size to the nuclear transfer increased (nt^1) mutant-glucocorticoid receptor in mouse lymphoma cells.¹²⁻¹⁸ These mutants contain a receptor mRNA that is reduced in size and therefore results in synthesis of a foreshortened receptor molecule.¹⁹

The present study was undertaken to determine the mechanism responsible for the $M_r \sim 52,000$ -receptor fragment in human leukemia cell cytosol. Our studies demonstrate for the first time that human leukemia cells contain a serine protease that digests the intact glucocorticoid receptor to a $M_r \sim 52,000$ -fragment. We find that glucocorticoid receptors in over 50 different leukemia cell samples are normal in size if diisopropylfluorophosphate, a potent inhibitor of serine proteases, is used to stabilize the receptor. Consistent with this observation, we find that the receptor mRNA in human leukemia cells has a normal size.

METHODS

Materials. All chemicals, including proteases, protease inhibitors, and unlabeled dexamethasone, were purchased from Sigma Chemical Co., St. Louis. Acrylamide, N,N'-methylenebisacrylamide, and Coomassie blue R-250 were from Bio-Rad Laboratories, Richmond, CA. The low mol wt standards kit for gel electrophoresis was purchased from Pharmacia Fine Chemicals, Piscataway, NJ. [6,7-³H]Dexamethasone-21-mesylate was from New England Nuclear, Boston.

Buffers. Phosphate buffered saline (PBS) was prepared as described previously.¹¹ The hypotonic buffer used in cytosol preparation consisted of 25 mmol/L Tris pH 8.2, 1 mmol/L EDTA, 10% glycerol, and 20 mmol/L Na₃MoO₄.

Cell Lines. The Victor human leukemia cell line (a B lymphoblast cell line) was given by Dr Robert Allen (American Red Cross, St. Louis). Mouse lymphoma cell lines and methods of cell culture were described previously.²⁰

Leukemia cell isolation. Human leukemia cells were isolated from either peripheral blood or bone marrow by Ficoll-Hypaque separation as described previously.¹¹ Only freshly isolated cells were used for experiments.

Affinity labeling. The method of labeling receptors in intact cells with [³H]dexamethasone mesylate was described in detail previously.¹¹ Briefly, cells were washed with PBS and resuspended in PBS in Eppendorf microcentrifuge tubes so that each tube contained 10 to 20 million cells. The cell suspensions were incubated for four hours at 4°C with 200 nmol/L [³H]dexamethasone mesylate. Duplicate cell suspensions contained either the radiolabeled steroid alone (labeled — in figures) or the radiolabeled steroid plus 100-fold excess unlabeled dexamethasone (labeled + in figures). At the end of the incubation period, the cells were pelleted and the cell pellets were frozen at -80°C for 15 minutes and then thawed in hypotonic buffer at 4°C for 15 minutes to prepare cytosol. The cytosol was then boiled for two minutes in the sample buffer for gel electrophoresis and subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) as detailed previously.¹¹ Gels were analyzed by autoradiography.¹¹ Molecular weight standards were phosphorylase b (97,400), bovine serum albumin (67,000), ovalbumin (45,000), carbonic anhydrase (30,000), trypsin inhibitor

(20,100), and lactalbumin (14,400). References for the mol wt values were given previously.¹¹

Protease inhibitors. To inhibit proteolysis of the affinity-labeled receptor during cytosol preparation, protease inhibitors were added to the hypotonic buffer immediately prior to use. Diisopropylfluorophosphate (DFP) was added to the hypotonic buffer to give a final concentration of 5 mmol/L. To exclude the possibility that the inhibitory effect of DFP was due to an impurity present in certain commercial preparations of DFP, samples of DFP were treated with cupric ion and imidazole to catalyze the hydrolysis of DFP.^{21,22} In other experiments a stock solution of phenylmethylsulfonylfluoride (PMSF) was prepared in absolute ethanol and added to the hypotonic buffer to give a final concentration of 10 mmol/L. Benzamidine was added to the hypotonic buffer to give a final concentration of 5 mmol/L. Aprotinin (2 mg/mL; 14.5 trypsin inhibitory U/mg) was added to the hypotonic buffer at a final dilution of 1:1000. A 100 mmol/L stock solution of iodoacetamide was added to the hypotonic buffer to give a final concentration of 1 mmol/L. A stock solution of 0.01 mol/L HgCl₂ was added to the hypotonic buffer to give a final concentration of 0.01 mM. The hypotonic buffer was prepared without EDTA when HgCl₂ was used.

Limited protease digestion. A concentrated solution of chymotrypsin in deionized water was prepared fresh for each experiment. An aliquot of the chymotrypsin solution was added to affinity-labeled cytosol and incubated at 25°C for 15 minutes. The cytosol was transferred to the gel electrophoresis sample buffer and boiled to stop the reaction.

RNA isolation and analysis. Total cellular RNA was isolated from leukemia cells by sedimentation through cesium chloride.²³ The RNA was analyzed by Northern blot hybridization using a cDNA for the rat liver glucocorticoid receptor as described previously.¹⁹

RESULTS

Affinity labeling human leukemia cell receptors. Human leukemia cells were isolated from peripheral blood or bone marrow and then incubated with [³H]dexamethasone mesylate to affinity label the glucocorticoid receptors. Cytosol was then prepared and subjected to SDS-PAGE to determine the mol wt of the affinity-labeled receptors. Multiple proteins in cells bind [³H]dexamethasone mesylate and therefore appear as bands on autoradiograms of gels. To distinguish the specific binding proteins, or receptors, from the nonspecific binding proteins, duplicate cell suspensions were incubated with [³H]dexamethasone mesylate in the presence or absence of 100-fold excess unlabeled dexamethasone. The unlabeled dexamethasone competes with the [³H]dexamethasone mesylate for binding to receptors but does not compete for binding to nonsaturable binding sites on other proteins. Therefore, on autoradiograms, band(s) that correspond to affinity-labeled receptor(s) can be distinguished from nonreceptor bands because the receptor bands are seen only in the absence of competing steroid (lane —) and are not seen in the presence of competing unlabeled steroid (lane +). Small differences in the amount of cytosol applied to the — lane and + lane on gels could give rise to apparent differences in the intensity of corresponding bands on the two lanes. Therefore, only those bands that differ markedly in intensity between — and + lanes are considered to be receptor bands. For clarity, receptor bands on autoradiograms are designated by an arrowhead.

We determined the mol wt of glucocorticoid receptors in

cytosol from 52 different human leukemia samples. Cytosol from all of the samples contained intact receptors that migrated opposite the phosphorylase b marker and therefore have been assigned a M_r of 97,000 (Fig 1). A major receptor fragment that consistently migrated to just above the ovalbumin standard ($M_r \sim 45,000$) was detected in cytosol from 24 of the 52 leukemia samples, as illustrated in Fig 1. We previously assigned this receptor fragment a M_r of 55,000.¹¹ We have now reanalyzed the previously reported results along with additional experiments reported here and find the M_r of this receptor fragment to be $52,000 \pm 500$ (mean $\pm$ SE, $N = 24$). Although the M_r 52,000-receptor fragment was the major receptor fragment detected in our studies, we cannot exclude the possibility that other minor receptor fragments may be present in the cytosol of leukemia cells. For example, a $M_r \sim 30,000$ -receptor fragment appeared to be present in the cytosol of three leukemia samples, one of which is shown in Fig 2.

$M_r \sim 52,000$ -receptor fragments were detected with approximately equal frequency in the different types of leukemia studied (Table 1). These receptor fragments were detected in the cytosol of leukemia cells from previously untreated patients (8/23, 35%) and previously treated patients (16/29, 55%).

Effect of protease inhibitors. To determine if the $M_r \sim 52,000$ -receptor is present within intact cells or if it is produced by proteolytic digestion of $M_r \sim 97,000$ -receptor during cytosol preparation, 5 mmol/L diisopropylfluoro-

Fig 1. Effect of DFP on glucocorticoid receptors. Human leukemia cells (acute lymphocytic leukemia) were incubated with [^{3} H]dexamethasone mesylate in the absence (-) or presence (+) of excess unlabeled dexamethasone to affinity label the glucocorticoid receptors. Cytosol was prepared using hypotonic buffer that either did not contain DFP (A) or did contain DFP (B). The cytosol was subjected to SDS-PAGE, and the gels were analyzed by autoradiography, as shown here. Arrowheads point to bands that represent affinity-labeled receptors.

Fig 2. Effect of chymotrypsin on glucocorticoid receptors. Same as Fig 3 except that leukemia cells from a different patient (chronic lymphocytic leukemia) were studied. (A) No chymotrypsin. (B) 5 μ g/mL chymotrypsin. (C) 10 μ g/mL chymotrypsin. Arrowheads point to bands that represent affinity-labeled receptor fragments. An additional receptor fragment appears to be located above the 30k marker protein.

phosphate (DFP) was included in the hypotonic buffer used for cytosol preparation. In cytosol samples that contained only $M_r \sim 97,000$ -receptors, the intensity of the receptor band on autoradiograms was not affected by inclusion of DFP in the hypotonic buffer (not shown). In samples that contained both $M_r \sim 97,000$ - and $M_r \sim 52,000$ -receptors, the inclusion of DFP in the hypotonic buffer eliminated the $M_r \sim 52,000$ -receptor band and increased proportionately the intensity of the $M_r \sim 97,000$ -receptor band (Fig 1). This finding indicates that the $M_r \sim 52,000$ -receptor band represents a receptor fragment produced from the $M_r \sim 97,000$ -receptor by proteolytic digestion during cytosol preparation. The ability of DFP to eliminate the $M_r \sim 52,000$ -receptor band was confirmed in ten separate experiments using leukemia cells from a different patient in each experiment. In no experiment did DFP fail to prevent formation of the $M_r \sim 52,000$ -receptor.

To determine the type of protease responsible for generat-

Table 1. Glucocorticoid Receptors in Human Leukemia Cells

Type of Leukemia	Receptor M_r		
	97,000	97,000 + 52,000	Total
Acute lymphoblastic	9	8	17
Acute nonlymphoblastic	9	8	17
Chronic lymphocytic	8	7	15
Chronic myelogenous, blast crisis	2	1	3

Values represent the number of leukemia cell samples that contained either $M_r \sim 97,000$ receptors or both $M_r \sim 97,000$ and $M_r \sim 52,000$ receptors.

ing $M_r \sim 52,000$ -receptor fragments in leukemia cytosol, a variety of protease inhibitors with different protease specificities were included in the hypotonic buffer used for cytosol preparation. Inhibitors that have major specificity for serine proteases (PMSF, aprotinin, and benzamide) and inhibitors that have major specificity for cysteine proteases (HgCl_2 and iodoacetamide) did not inhibit receptor digestion (not shown). Certain preparations of DFP are contaminated with a factor that inhibits cysteine proteases.^{21,22} The serine protease inhibitory activity of DFP is eliminated by hydrolysis, but the cysteine protease inhibitory activity is stable upon hydrolysis.^{21,22} DFP that was hydrolyzed to eliminate its serine protease inhibitory activity did not block the generation of $M_r \sim 52,000$ -receptors (not shown). In addition, in studies that are not shown, DFP did not inhibit receptor digestion by the cysteine protease papain. Therefore, the protease responsible for digestion of the intact leukemia cell receptor to a $M_r \sim 52,000$ -fragment appears to belong to the serine class of proteases.

Limited protease digestion. Limited digestion of normal size glucocorticoid receptors with chymotrypsin is known to separate the immunoactive domain from the steroid-binding and DNA-binding domains of the receptor molecule.^{24,25} To determine if the endogenous protease in human leukemia cells digests the glucocorticoid receptor at the same site as chymotrypsin, [^3H]dexamethasone mesylate-labeled cytosol from human leukemia cells was incubated with a range of concentrations of chymotrypsin prior to gel electrophoresis. In cytosol that contained only $M_r \sim 97,000$ -receptors, chymotryptic digestion produced a $M_r \sim 40,000$ -receptor fragment (Fig 3). In cytosol that contained both $M_r \sim 97,000$ -

and $M_r \sim 52,000$ -receptors, chymotryptic digestion eliminated both the $M_r \sim 97,000$ - and the $M_r \sim 52,000$ -receptors and produced a $M_r \sim 40,000$ -receptor fragment (Fig 2). These results indicate that the endogenous leukemia cell protease digests the glucocorticoid receptor at a different site than does chymotrypsin and that the $M_r \sim 52,000$ receptor fragment in leukemia cytosol contains the chymotrypsin sensitive site that is present in the intact $M_r \sim 97,000$ receptor.

Mixing studies. To further substantiate that proteolysis was responsible for producing the $M_r \sim 52,000$ receptor fragment, cells of the Victor human leukemia cell line were incubated with [^3H]dexamethasone mesylate and then mixed with unlabeled fresh human leukemia cells immediately prior to cytosol preparation. The human leukemia cells were preincubated with $20 \mu\text{mol/L}$ unlabeled dexamethasone to prevent their receptors from binding the [^3H]dexamethasone mesylate. A typical experiment is shown in Fig 4. This experiment employed the same human leukemia cell sample that was employed in the experiment shown in Fig 2. In the absence of added human leukemia cells, cytosol from the Victor cells contained only $M_r \sim 97,000$ -receptors. The addition of the unlabeled human leukemia cells to the affinity-labeled Victor cells prior to cytosol preparation generated $M_r \sim 52,000$ -receptor fragments from the intact affinity-labeled receptors.

The leukemia cell samples employed in this study contained variable numbers of red blood cells and platelets. To

Fig 3. Effect of chymotrypsin on glucocorticoid receptors. Receptors in human leukemia cells (chronic lymphocytic leukemia) were affinity labeled as described in Fig 1. The cytosol was incubated at 25°C for 15 minutes with chymotrypsin prior to SDS-PAGE. (A) No chymotrypsin. (B) $5 \mu\text{g/mL}$ chymotrypsin. (C) $10 \mu\text{g/mL}$ chymotrypsin. Arrowheads point to bands that represent affinity-labeled receptors or receptor fragments.

Fig 4. Mixing studies. Glucocorticoid receptors in Victor cells were affinity-labeled as described in Fig 1. Leukemia cells (chronic lymphocytic leukemia) from the same sample used in Fig 2 were incubated for four hours with $20 \mu\text{mol/L}$ unlabeled dexamethasone. The unlabeled cells were then mixed with the affinity-labeled Victor cells in a ratio of 3:1 immediately prior to cytosol preparation. Cytosol was then analyzed by SDS-PAGE as described in Fig 1. (A) Victor cells with no addition. (B) Victor cells plus unlabeled leukemia cells. Arrowheads point to bands that represent affinity-labeled receptors or receptor fragments.

determine if red blood cells or platelets, rather than leukemia cells, could be the source of the protease that digests receptors to the $M_r \sim 52,000$ -fragment, experiments were performed in which human red blood cells or human platelets were added to affinity-labeled leukemia cells prior to cytosol preparation. The admixture of these cells did not produce receptor degradation (data not shown).

Receptor mRNA. Receptor mRNA from human cell samples was compared to receptor mRNA from mouse lymphoma cell lines. Glucocorticoid receptor mRNA in six different human leukemia cell samples was analyzed by Northern blot hybridization using a receptor cDNA for the rat liver glucocorticoid receptor, and results from four of these samples are shown in Fig 5. A normal 6.5-kilobase (kb) receptor mRNA was observed in human cells that contain both normal size receptors and the $M_r \sim 52,000$ -fragments. The patient samples containing $M_r \sim 52,000$ -receptor fragments (lanes 5, 6, 7) have receptor mRNA that looks identical to the mRNA from the patient sample containing only intact receptors (lane 2). The faintness of the 6.5 kb bands in lanes 5 and 7 may reflect lower levels of receptor

mRNA in these leukemia samples or degradation of the RNA during preparation. The wild type S49 mouse lymphoma cells, which have normal size ($M_r \sim 97,000$) glucocorticoid receptors, have a 6.5 kb receptor mRNA (lane 4). The nt^1 mutant mouse lymphoma cells (S49.143r), which have smaller than normal glucocorticoid receptors ($M_r \sim 48,000$), have a 5.0 kb receptor mRNA. We conclude that the receptor mRNA in human leukemia cells is the expected size regardless of the mol wt of receptors in cytosol preparations, unlike the highly characterized 5.0 kb receptor mRNA present in nt^1 mutant mouse lymphoma cells.¹⁹

DISCUSSION

We demonstrate that cytosol from human leukemia cells frequently contains steroid binding receptor fragments that have a M_r of $\sim 52,000$ in addition to intact receptors that have a M_r of $\sim 97,000$. Several samples also appeared to contain $M_r \sim 30,000$ -receptor fragments. The present study provides two types of evidence that prove that the $M_r \sim 52,000$ -receptor fragment arises from the intact normal size receptor by proteolytic digestion during cytosol preparation. First, formation of the $M_r \sim 52,000$ -receptor fragment was blocked by inclusion of the potent protease inhibitor DFP in the hypotonic buffer used for cytosol preparation. Second, admixture of fresh unlabeled human leukemia cells to an affinity-labeled human leukemia cell line prior to cytosol preparation resulted in digestion of the intact affinity-labeled receptors to $M_r \sim 52,000$ -receptor fragments. We previously reported similar mixing studies to be negative.¹¹ This led us to the incorrect conclusion that proteolysis was not responsible for the formation of $M_r \sim 52,000$ -receptor fragments in the cytosol of human leukemia cells. The previous mixing studies involved the mixture of cytosol samples that had been stored at -80°C rather than the mixture of fresh intact cells as in the present study. Therefore the failure of the earlier mixing studies to demonstrate receptor proteolysis suggests that the leukemia cell protease responsible for receptor digestion may not be stable upon storage at low temperatures.

Limited digestion of the normal glucocorticoid receptor by chymotrypsin is known to separate the immunoactive domain of the receptor from the steroid-binding and DNA-binding domains.^{24,25} The leukemia cell protease described here must digest the intact $M_r \sim 97,000$ glucocorticoid receptor at a different site than does chymotrypsin, since chymotryptic digestion of the intact receptor produced a $M_r \sim 40,000$ -receptor fragment (Fig 3). The $M_r \sim 52,000$ -receptor fragment in human leukemia cell cytosol could be digested to a $M_r \sim 40,000$ -receptor fragment by chymotrypsin, indicating that the $M_r \sim 52,000$ -receptor fragment retains the chymotrypsin sensitive site that is present in normal receptors (Fig 2).

The $M_r \sim 52,000$ -receptor fragment was detected in leukemia cell samples obtained from 24 of 52 different patients. The presence of the $M_r \sim 52,000$ -receptor fragment was consistent when leukemia cell samples were obtained again from the same patient at time intervals of up to 1 year. We previously demonstrated that receptor digestion does not occur in some leukemia cell cytosol samples even when

Fig 5. Northern blot analysis of leukemia cell receptor RNA. Total cellular RNA from five human samples (lanes 1, 2, 5-7) and two murine samples (lanes 3, 4) were blotted with a probe from the 5' region of the rat glucocorticoid receptor cDNA¹⁹ (Miesfeld et al, unpublished data). Lane 1 (HeLa cells), lane 2 (human leukemia cells), and lane 4 (mouse lymphoma cells S49.A2;wt) show the 6.5-kb receptor RNA present in cells containing only $M_r \sim 97,000$ receptors. Lanes 5, 6, 7 (human leukemia) and lane 3 (mouse lymphoma S49.143r; nt^1) contain RNA from cells that also possess a smaller receptor protein of $M_r \sim 48,000$ to $52,000$. The nt^1 -specific receptor RNA is shown as a 5.0-kb transcript (lane 3). The nature of the smear around 4 kb is unclear, but it appears to be due to partially degraded RNA.

proteolysis is encouraged by prolonged incubation or incubation at 25 °C to 37 °C.¹¹ The reason receptor digestion occurs in some but not all human leukemia cell samples is unknown. It is possible that the protease responsible for receptor degradation may not be present in all leukemia cells or that some leukemia cells may contain a naturally occurring protease inhibitor that protects the receptor from proteolysis. Alternatively, the protease activity may be similar in all leukemia cells but some leukemia cells may contain glucocorticoid receptors that are abnormally sensitive to digestion by the protease. We are attempting to distinguish between these possibilities at the present time. Receptor digestion does not occur in normal human peripheral blood mononuclear cell samples under the assay conditions employed here.¹¹ However, we have observed receptor digestion to a $M_r \sim 52,000$ -fragment when normal human peripheral blood mononuclear cell cytosol is incubated for two hours at 25 °C (data not shown). Receptor digestion under these conditions is inhibited by DFP. Therefore, the protease responsible for receptor digestion may not be unique to leukemia cells but appears to be present, although probably at a lesser activity, in normal peripheral blood mononuclear cells.

The $M_r \sim 52,000$ -receptor fragment described here is similar in size to the defective receptors present in cytosol from nt^1 mutant mouse lymphoma cell lines.^{13,16-18} This observation raised the possibility that the receptor abnormality in human leukemia cells and in the nt^1 mutant mouse lymphoma cells may involve a common mechanism.¹¹ In this regard there is some evidence that glucocorticoid receptors in intact nt^1 mutant cells are normal in size and undergo degradation during cytosol preparation.²⁶ However, the receptor abnormalities in human leukemia cells and in nt^1 mutant mouse lymphoma cells differ in several respects. First, a variety of different protease inhibitors, including DFP, do not inhibit the formation of defective receptors in cytosol from nt^1 mutant mouse lymphoma cells (Distelhorst et al, unpublished data). Second, the $M_r \sim 52,000$ -receptor in human leukemia cells contains a chymotrypsin-sensitive site, whereas the defective receptors in nt^1 mutant mouse lymphoma cells are relatively resistant to digestion by chymotrypsin¹⁷ (Distelhorst et al, unpublished observations). Third, the receptor mRNA in nt^1 mutant mouse lymphoma cells is decreased in size compared to the size of receptor mRNA in wild type cells.¹⁹ In the present study we show that the size of receptor mRNA in human leukemia cells appears to be normal whether or not the $M_r \sim 52,000$ -receptor fragment is observed. Therefore abnormalities of glucocorticoid receptor mRNA, which may give rise to the synthesis of foreshortened receptors in certain mutant mouse lymphoma cells, are apparently absent from human leukemia cells.

Stevens et al²⁷ showed that glucocorticoid receptors in chronic lymphocytic leukemia cells are often degraded to a form having a Stokes radius of 3.5 nm. According to the work of Sherman et al,⁹ a receptor fragment of this size would be expected to have a $M_r \sim 40,000$ to 60,000. Therefore it is possible that the $M_r \sim 52,000$ -receptor fragment described by us is the same as the lower mol wt form of the receptor described previously by Stevens et al.²⁷ Sherman et al⁷ and Holbrook et al^{5,8} found that cytosol from human leukemia

cells frequently contained meroreceptors in addition to normal size receptors. The meroreceptor, described by Sherman et al⁹ in rat liver and kidney cytosol, represents a degraded receptor that has a $M_r \sim 20,000$ to 25,000. Although similar size receptor fragments ($M_r \sim 30,000$) were detected in several leukemia samples studied here, the major receptor fragment observed in the present study was significantly larger ($M_r \sim 52,000$). There are two potential explanations for the difference in size between receptor fragments detected in the present study and earlier studies. First, we analyzed receptors under reducing and denaturing conditions by gel electrophoresis, whereas the size of receptors in earlier studies was measured under nondenaturing conditions by gel filtration. Mendel et al²⁸ demonstrated that gel electrophoresis under denaturing conditions is a more sensitive technique for detecting intermediate size receptor fragments ($M_r \sim 50,000$) than is gel filtration under nondenaturing conditions. Second, in the present study, cytosol samples were incubated for only a brief period of time (~ 30 minutes) prior to gel electrophoresis, whereas the assay methods employed in earlier studies required cytosol incubations for longer periods of time, thus permitting more extensive receptor degradation.

Although we tested a variety of protease inhibitors with different specificities for serine and cysteine proteases, only DFP inhibited receptor digestion to the $M_r \sim 52,000$ -fragment. Although the major effect of DFP is to inhibit serine proteases, commercial preparations of DFP often contain an impurity that inhibits cysteine proteases.^{21,22} The serine protease inhibitory activity of DFP is sensitive to hydrolysis, whereas the cysteine protease inhibitory activity is resistant to hydrolysis.^{21,22} Since hydrolyzed DFP did not inhibit generation of the $M_r \sim 52,000$ -receptor fragment, it appears that the protease responsible for receptor digestion belongs to the serine class of proteases. The leukemia cell protease that generates the $M_r \sim 52,000$ -receptor fragment may be different from the protease responsible for meroreceptor formation in leukemia cytosol, since the latter has been reported to be a "lysine specific" protease.^{7,10}

Mendel et al²⁸ showed that intact glucocorticoid receptors in rat thymus cytosol are converted to a $M_r \sim 52,000$ -receptor fragment when the cytosol is incubated at 3 °C for two hours. Proteolysis of the rat thymus glucocorticoid receptor is prevented by calpastatin, an inhibitor of calcium activated cysteine proteases.²⁹ Therefore it appears that receptor proteolysis in rat thymus cells is due to the activity of a calcium-activated cysteine protease.^{28,29} It seems unlikely that the same protease is responsible for digestion of the human leukemia receptor to a $M_r \sim 52,000$ -receptor fragment for the following reasons. First, idoacetamide, an inhibitor of calcium-activated cysteine proteases in mammalian cells,³⁰ did not inhibit human leukemia cell-receptor digestion. Second, the hypotonic buffer used for cytosol preparation in the present study contained EDTA, which would be expected to inactivate calcium-activated proteases. Third, under the assay conditions employed in the present study, intact receptors in rat thymus cells are stable, even when cytosol is incubated for two hours at 4 °C (Distelhorst et al, unpublished observations).

Protease inhibitors are known to affect glucocorticoid receptor binding, inactivation, degradation, and transformation *in vitro*.³¹ However, the effect of protease inhibitors on glucocorticoid receptor function *in vivo* is unknown. We are currently isolating and characterizing the serine protease from human leukemia cells that produces the $M_r \sim 52,000$ -receptor fragment. Also, we are trying to determine if this

protease affects the function or turnover of glucocorticoid receptors *in vivo*.

In Vitro and In Vivo Effects of Deferoxamine in Neonatal Acute Leukemia

By Zeev Estrov, Akio Tawa, Xin-Hua Wang, Ian D. Dubé, Hassan Sulh, Amos Cohen, Erwin W. Gelfand, and Melvin H. Freedman

A six week old infant with acute leukemia failed to attain remission with chemotherapy. Because we previously demonstrated that the iron chelator deferoxamine (DFO) has antiproliferative properties and modulatory effects on cell differentiation, a protocol was designed for in vitro study and for clinical use in the patient. At diagnosis, blast cells were morphologically undifferentiated, had nondiagnostic cytochemistry, showed an abnormal karyotype ($t[4;11]$), expressed markers of B cell lineage, and demonstrated $C\mu$ gene rearrangement. Tissue culture of marrow or blood cells yielded colonies of leukemic blasts. Increasing concentrations of DFO produced a dose-dependent suppression of patient's blast colony growth in vitro, and blasts within colonies showed a marked change in surface antigen expression from lymphoid to myelomonocytic

markers, became monocytic in appearance, and developed intense staining for nonspecific esterase. When DFO was given intravenously to the patient as a single agent for 48 hours, blasts no longer expressed lymphoid antigens and became strongly positive for myelomonocytic markers, identical to the in vitro findings. Intravenous DFO halted rising peripheral blood blast cell numbers and allowed a several-fold increase in normal hematopoietic progenitor colony growth. When combined with low-dose cytosine arabinoside in the treatment protocol, DFO caused striking leukemic cytoreduction. Our findings indicate that DFO has antileukemic properties by virtue of its effects on proliferation and differentiation, and they prompt further experimental and clinical studies with this agent.

©1987 by Grune & Stratton, Inc.

DEFEROXAMINE (DFO) is widely used therapeutically as a chelator of ferric iron in disorders of iron overload.¹ As we previously demonstrated, this drug is a potent inhibitor of DNA synthesis by human B and T lymphocytes in vitro.² Micromolar concentrations of DFO decreased intracellular levels of deoxyribonucleoside triphosphates and prevented cells from going beyond early S-phase of the cell proliferation cycle.² We also found that DFO could irreversibly inhibit proliferation and colony formation in the leukemia cell line HL-60 and could induce differentiation and DNA damage in these cells.³

Based on these properties we administered DFO for the treatment of acute leukemia in a 6-week-old patient with the disease. Studies performed on the patient's peripheral blood (PB) and bone marrow (BM) confirmed the antiproliferative properties of DFO in vitro and in vivo, as well as modulatory effects on leukemic cell differentiation.

CASE REPORT

A 6-week-old female infant was assessed for a paroxysmal harsh cough and was found to have a marked leukocytosis. She was the product of a normal full-term pregnancy, and the neonatal course was unremarkable. On physical examination she appeared well. The chest was clear to auscultation. Spleen tip and liver edge were palpable. There was no lymphadenopathy.

Her blood counts were as follows: hemoglobin 13.3 g/dL, white blood cells 94,500/ μ L with blasts comprising 52,400/ μ L, platelets 295,000/ μ L. Values for urea, creatinine, electrolytes, and uric acid levels were normal. Serum proteins, bilirubin, alkaline phosphatase and glutamic oxaloacetic transaminase levels were also normal. Cerebrospinal fluid was acellular with normal chemistry.

A bone marrow aspirate confirmed leukemic cell replacement. Blast cells were morphologically undifferentiated. Cytochemistry testing was negative for periodic-acid Schiff (PAS), Sudan-black, nonspecific esterase, and acid phosphatase. Immunologic marker studies on the diagnostic marrow cells were suggestive of B cell origin: Ia, 80%; B-4, 68%; BA-1, 14%; BA-2, 50%; B-1, negative; common acute lymphoblastic leukemia antigen (CALLA), negative; cytoplasmic IgM (cIgM), negative; surface immunoglobulin (sIg), negative. Myelomonocytic markers (MO-1, My906, My-4) T cell markers (Leu-1), and E rosette formation were all negative. Further evidence that the blast cells were derived from B cell precursors was

based on studies of immunoglobulin gene rearrangement. Following restriction enzyme digestion, a $C\mu$ probe recognized a rearrangement of one μ chain allele.⁴ Cytogenetic analysis of 26 metaphases from unstimulated marrow culture for 24 hours revealed a normal female karyotype (46XX in four cells) and a clone bearing a translocation involving the long arms of chromosomes 4 and 11 (in 22 cells). The breakpoint in chromosome 4 was in the region q21 and in chromosome 11 in the region q23.

A diagnosis of acute lymphoblastic leukemia (ALL) was made and a four-week chemotherapy treatment protocol was started: vincristine IV weekly $\times$ 4 (0.75 mg/ m^2 /dose); prednisone 2 mg/kg/day PO; daunomycin IV weekly $\times$ 3 (12.5 mg/ m^2 /dose); L-asparaginase intramuscularly (IM) 3 $\times$ weekly for nine doses (6,000 U/ m^2 /dose); and cytosine-arabioside (ARA-C) intrathecally $\times$ 1 dose, 7.5 mg total. At the conclusion of therapy peripheral blasts were still present, and a repeat marrow aspirate confirmed failure to attain remission. PB and BM blasts expressed identical immunologic markers to those demonstrated on cells from the original marrow.

With informed consent and following approval by the Human Experimentation Committee of our institution, an experimental protocol was initiated: DFO was diluted in normal saline and given by continuous infusion 10 mg/kg/h; ARA-C was given by IV push, 5 mg/kg/dose. When used together, DFO was stopped eight to 12 hours prior to ARA-C (Table 1).

*Deferoxamine (DFO) was given by continuous IV infusion in normal saline, 10 mg/kg/h; Cytosine-arabioside (ARA-C) was given by IV push, 5 mg/kg/dose.

MATERIALS AND METHODS

Deferoxamine. Deferoxamine (CIBA-GEIGY, Mississauga, Canada) was dissolved in iron-free RPMI culture medium (Ontario Cancer Institute, Toronto) and added to cell cultures in final concentrations of 0.75 to 2.15 $\mu\text{mol/L}$.

Preparation of cells. Heparinized BM or PB cells were layered over Ficoll-Paque (Pharmacia Fine Chemicals, Piscataway, NJ) and centrifuged ($200 \times g$, 4°C) for 20 minutes to eliminate neutrophils and red cells.

CFU-GEMM assay. The CFU-GEMM assay was performed according to Fauser and Messner^{5,6} with slight modifications. Briefly, 2×10^5 nucleated PB cells were cultured in methylcellulose with iron-free RPMI (Ontario Cancer Institute, Toronto), 30% AB serum, 5% leukocyte-conditioned medium prepared with phytohemagglutinin (PHA-LCM),⁷ human erythropoietin 1.0 U/mL (British Columbia Cancer Research Institute, Vancouver, BC), and 5×10^5 mol/L 2-mercaptoethanol. One milliliter of the culture mixture was placed in 35-mm Petri dishes (Becton Dickinson, Oxnard, CA) and was incubated at 37°C with 5% CO_2 in air in a humidified atmosphere. All cultures were evaluated after 14 days for the number of BFU-E colonies, defined as an aggregate of more than 500 hemoglobinized cells or three or more erythroid subcolonies, CFU-C colonies of at least 40 granulocytic or macrophage cells or both, and mixed colonies containing all elements. Individual colonies were plucked from the cultures with a micropipette and analyzed for cellular composition and immunologic markers.

ALL blast colony assay. The assay used was a modification of previously described methods.^{8,9} T cells were depleted from BM or PB by standard rosetting techniques using sensitized sheep erythrocytes.¹⁰ Feeder cells for the culture were prepared from PB of normal donors by depleting the adherent fraction¹¹ and exposing it to 7,000 rads to prevent cell proliferation.

Phytohemagglutinin-conditioned medium (PHA-TCM) was prepared from the T cell PB fraction obtained from a patient with

hemochromatosis undergoing therapeutic phlebotomies as previously described.⁸

Cell culture procedure. 2×10^5 T depleted PB cells were suspended in RPMI, 10% FCS, 10% PHA-TCM, irradiated feeder cells ($10^5/\text{mL}$), and methylcellulose at a final concentration of 0.9% in 35-mm Petri dishes. The culture dishes were placed into a specialized modular incubator chamber (Billups-Rosenberg, Del Mar, CA) in a humidified atmosphere of 5% O_2 , 5% CO_2 , and balanced nitrogen. After six days of incubation, colonies were counted. A cluster of more than 20 cells was defined as a colony. Individual colonies were plucked from the culture plates and smeared on glass slides for further evaluation, using Wright's stain and nonspecific esterase staining.¹² For control, 2×10^5 irradiated feeder cells were cultured in the same assay system in each experiment to exclude their potential for colony formation.

Surface Markers

Immunocytochemical method. The cell surface antigens of air-dried smears were detected using monoclonal antibodies (MoAbs) and intestinal alkaline phosphatase, as previously described.¹³⁻¹⁵ This assay was performed to detect surface antigens on patients' PB and BM smears and colonies plucked from cultures. For colony characterization, each MoAb was tested on five to ten individual colonies that had been plucked at random from a culture plate and smeared on a glass slide. The slides were counterstained in hematoxylin for light microscopy, and the presence of surface antigen was indicated as bright red granular cellular inclusions. Morphological details were well preserved, and a high degree of correlation between morphology and surface antigen expression was observed. The intensity of staining was defined as strong (+++), moderate (++), and weak (+).

Immunofluorescence method. The cell surface phenotype was determined by indirect cell-surface fluorescence; a fluorescein-conjugated goat antimouse IgG (Fab), was used as second antibody. For each MoAb tested, 1×10^6 cells were stained and 200 cells examined. The labeling was performed on ice in the presence of 0.05% sodium azide. The percentage of cells with surface fluorescence was determined by counting cells using an inverted phase-fluorescent microscope.

Monoclonal antibodies. The following MoAbs were used in these studies: anti-OK1a (Ortho Diagnostic Systems, Raritan, NJ) to detect HLA-D framework antigen; anti-MY-7, anti-Mol and anti-MY-4 (Coulter Immunology, Hialeah, FL) to identify myelomonocytic markers; anti-BA1, anti-BA2, anti-B1 and anti-B4 (Becton Dickinson, Oxnard, CA) to recognize cells of the B cell lineage; anti-J5 (Coulter Immunology) to recognize cells bearing common ALL (CALLA) antigen; and anti-Leu-1 and anti-Leu-4 (Coulter Immunology) to recognize cells of the T cell lineage.

RESULTS

In Vitro

Blast colony assay. Prior to therapy with DFO, patient's PB blast cells were cultured using the ALL blast colony assay; they yielded a mean of 700 colonies/ 2×10^5 cells plated. Individual colonies were plucked from the culture plates and were examined for cellular composition. Morphologically they were undifferentiated blast cells identical to the appearance of marrow cells at diagnosis. The cells were negative for nonspecific esterase by cytochemistry. Surface antigen studies of PB cells confirmed lymphoblastic markers and absent myelomonocytic markers (Table 2).

Antiproliferative effect of DFO. As shown in Fig 1, when increasing concentrations of DFO were added to

Table 2. Surface Marker Analysis of Leukemia Cell Colonies (% Positive Cells)

	Control	2.5 μ mol Deferoxamine
Ia	80% (+++)	80% (+++)
CALLA	0%	0%
B4	80% (+++)	30% (+++)
Mol	0%	>90% (+++)
MY-4	0%	60% (++)
Leu-1	0%	0%
Leu-4	0%	0%

PB leukemia cell colonies were plucked at random from cultures containing 2.5 μ mol deferoxamine and were compared to cultures without deferoxamine using the immunocytochemical assay.

cultures of patient's PB blast cells, there was a dose-dependent suppression of blast colony growth. Significant decline in blast colonies was observed with DFO concentrations greater than 1.25 μ mol, and with 2.15 μ mol DFO, a 70% reduction in blast colonies was observed. In a control study of normal marrow obtained from a healthy volunteer, DFO also produced a dose-dependent suppression of normal hematopoietic colonies, CFU-C, CFU-E, and BFU-E. However, 10 μ mol DFO was necessary to achieve a 70% reduction in colony counts.

DFO and blast cell differentiation. Individual blast colonies from the culture plates containing DFO 2.5 μ mol were characterized (Table 2). Compared to colonies grown without exposure to DFO, a marked change in cell surface antigen expression was observed. Blast colonies from the DFO plates strongly expressed the myelomonocytic markers Mol and MY-4 as determined by immunocytochemistry, and numbers of B-4 positive cells were markedly reduced. Moreover, individual cells from colonies exposed to DFO were changed in morphology, appearing monocytic, and stained intensely for nonspecific esterase that could be inhibited by fluoride.

In Vivo

DFO was administered therapeutically according to the protocol outlined in Table 1.

DFO and blast cell differentiation. After 48 hours of continuous infusion of DFO as a single agent, striking changes in blast cell surface markers were detected immunocytochemically (Table 3). Prior to treatment no blasts expressed Mol antigen, and only 8% weakly expressed MY-4. After 48 hours cells expressing these two antigens, Mol and MY-4, were detected in peripheral blood blast cells. Concomitantly with DFO therapy there was a sharp decline

Table 3. Surface Marker Analysis Pre- and Post-Therapy (% Positive Cells)

	Before Deferoxamine Treatment	After Deferoxamine Treatment
Ia	80% (+++)	80% (+++)
CALLA	2% (+)	0% (+)
B4	37% (++)	0%
Mol	0%	40% (+++)
MY-4	8% (+)	60% (+++)
Leu-1	0%	0%
Leu-4	0%	0%

Immunologic surface markers were determined before and after 48 hours of deferoxamine treatment on PB smears using the immunocytochemical method.

from 37% to 0% of cells bearing B4 antigen. These data were confirmed by immunofluorescence studies.

At the conclusion of the 20-day treatment protocol, a marrow aspirate showed 60% blasts that were negative for PAS, Sudan-black, and acid phosphatase. In contrast to the marrow aspirate prior to DFO therapy, 60% of the blasts were positive for nonspecific esterase, and staining could be inhibited by fluoride. Surface marker studies performed concurrently demonstrated expression of myelomonocytic antigens that were not detected in marrow cells prior to treatment (Table 4).

Antiproliferative effect of DFO. The WBC and blast number had increased several-fold in the three days prior to DFO treatment (Table 1). After the first 48 hours of DFO therapy, the counts reached a plateau. Significant decline of WBC and blast numbers was observed on day 8, that is, six days following combination DFO-ARA-C therapy. By day 15, PB blasts almost completely disappeared.

Several CFU-GEMM assays were performed on PB during the first 48 hours of DFO treatment (Table 5). Impressive increases in normal hematopoietic progenitor colony growth were documented. Erythroid and granulocytic progenitor colony formation increased several-fold over pre-DFO treatment colony numbers.

Table 4. Surface Marker Analysis Before and at Conclusion of 20-Day Treatment (% Positive Cells)

	Before Deferoxamine Treatment	After Deferoxamine Treatment
Ia	80%	75%
slg	10%	0%
BA-1	14%	0%
BA-2	50%	0%

CFU-C	45 ± 6	126 ± 17
Mixed	1 ± 1	5 ± 2

CFU-GEMM colony culture of patient's PB was performed before and after 48 hours deferoxamine treatment.

DISCUSSION

The infant who was studied had leukemia that was unresponsive to conventional chemotherapy. At the conclusion of induction therapy, blasts were still present in PB and in marrow, and when chemotherapy was stopped, PB blast counts increased several-fold in three days.

The blasts were undifferentiated according to morphological and cytochemical criteria and expressed antigens of B lineage at diagnosis. Further confirmation of their origin from B cells was by analysis of DNA from the leukemic cells that revealed rearrangement of one of the immunoglobulin heavy-chain genes. The presence of an abnormal karyotype, t(4;11), as found on cytogenetic analysis of BM cells, has been previously reported in neonatal ALL.¹⁶ This form of leukemia is characterized by PB leukocytosis, blast cells with an undifferentiated appearance, and poor prognosis.¹⁷ Although the cytogenetic abnormality has been found in ALL,¹⁸ it has also been seen in cases of acute leukemia of myelomonocytic lineage.¹⁷

We were prompted to use DFO in an experimental treatment protocol because of our previous finding that the agent was a reversible early S-phase inhibitor of human lymphocyte proliferation.² Although widely used as a chelator of ferric iron in disorders of iron overload, we demonstrated that the drug is a potent inhibitor of DNA synthesis by B and T lymphocytes in vitro, likely by impairing the activity of the iron-containing enzyme ribonucleotide reductase through a chelating mechanism.² More recently we have shown that DFO can induce monocyte-macrophage cell differentiation in the human promyelocytic leukemic cell line, HL-60, as judged by altered expression of cell surface antigens, nonspecific esterase activity, and morphological changes combined with irreversible inhibition of colony formation.³ The mechanism appeared to be related to inhibition of replicative DNA synthesis or due to an increase in number of single-strand DNA breaks. Because DFO has antiproliferative properties as well as modulatory effects on cell differentiation, it may be potentially useful for experimental and therapeutic applications.

In vitro we were able to demonstrate the antiproliferative effects of DFO on leukemic cell growth from our patient using a blast colony assay. Because the plating efficiency of PB blast cells was very high, clear-cut suppression of colony growth by DFO could be readily demonstrated. The DFO-induced change in blast cell surface antigen expression from lymphoid to myelomonocytic was striking and confirmed the modulatory effect of DFO on cell differentiation.

The in vitro changes correlated closely with the findings during the first 48 hours of continuous infusion of DFO when used as a single agent. The PB WBC and blast counts, which

had risen dramatically for three days prior to DFO therapy, leveled off 48 hours after initiation of DFO infusion, suggesting an in vivo antiproliferative effect. Moreover, surface marker antigen changes were observed on the blast cells that were identical to those seen after DFO treatment in vitro. There was convincing evidence for expression of myelomonocytic antigens and concurrent disappearance of lymphoid markers. The possibility that during the 48 hours of DFO treatment a change in PB cell distribution was responsible for the change in surface markers was unlikely, since the blast count remained stable during this period. With the HL-60 cell line, Boyd and Metcalf showed that the differentiation process is associated with irreversible loss of proliferative ability, inhibition of DNA synthesis, and G₀/G₁ cell cycle arrest.¹⁹ Since identical changes in the same cell line were induced by DFO,³ this could be the mechanism by which DFO affected our patient's leukemic cells. Although the loss of proliferative ability was suggested by our data, it was not definitively proven using the colony assay technique.

The cellular lineage of the blasts is an important aspect of the case because there was a change in differentiation markers with therapy. It is unlikely that two separate leukemic populations were responsible for the dual marker findings because the abnormal karyotype found at diagnosis was still detected at the conclusion of therapy, suggesting persistence of the same leukemic clone. There have been reports of conversion with chemotherapy of cases of non-T ALL to myelomonocytic leukemia²⁰ and from T-lymphoblastic leukemia to promyelocytic leukemia.²¹ In the latter case it was shown that the leukemia was actually derived from a stem cell.²¹ Although we have observed the pattern of immunoglobulin heavy-chain gene rearrangement only in cases of ALL,⁴ the abnormal karyotype found in our patient's blast cells has been seen in both ALL and in ANLL.^{16-18,20} Moreover, the 4;11 translocation is remarkable for its association with biphenotypic expression of differentiation markers.²²⁻²⁴ In our case it is possible that the blasts showed "lineage infidelity"²⁵ and expressed markers from two lineages at different times. With regard to the mechanism, one may speculate that the 4;11 syndrome is a stem cell disorder that can differentiate along one lineage given a set of growth factors and in another lineage given others.

A low plating efficiency of normal pluripotent hematopoietic precursors in acute leukemia, as demonstrated in our patient, has been previously described.^{26,27} The significantly higher plating efficiency observed using the CFU-GEMM assay of erythroid as well as granulocyte-macrophage elements from our patient's PB following DFO treatment occurred in spite of persistently high numbers of PB blast cells. It is unlikely that a high percentage of the blast-like cells were actually normal hematopoietic progenitors because of their increased numbers and morphological features. It is possible that DFO in vivo induced a change in the leukemic blasts allowing their differentiation toward the erythroid as well as the granulocyte-macrophage lineage as previously described in Ph⁺-positive chronic myelogenous leukemia.^{28,29} Another interpretation is that DFO treatment in some manner permitted the proliferation of normal hema-

topoietic progenitors that were suppressed by the leukemic cells as described by Broxmeyer et al.^{30,31}

The rationale for using ARA-C with DFO in the treatment protocol was based on the hypothesis that if DFO could reversibly block leukemic cells in S-phase, after removal of DFO, ARA-C should destroy the cells progressing through S-phase because its cytotoxic action is S-phase-dependent.

From the available data it is still unclear whether the apparent synergism between DFO and ARA-C is attributed to S-phase synchronization or to the differentiating action of DFO. The marked clinical reduction in PB blast numbers, the changes in leukemic cell marker expression, and the in vitro and in vivo antiproliferative properties prompt further experimental and clinical studies with DFO.

Activation of Neutrophil Superoxide Production by Concanavalin A Can Occur at Low Levels of Intracellular Ionized Calcium

By John C. Whitin, Kazuhiko Takahashi, and Harvey J. Cohen

The effect of concanavalin A (Con A) on the concentration of ionized intracellular calcium ($[Ca_i^{++}]$) in human granulocytes (PMN) was monitored using the fluorescent calcium indicator and chelator, Quin2. The addition of Con A to PMN resulted in a rise in $[Ca_i^{++}]$ that was markedly enhanced by the presence of Ca^{++} in the external buffer. The onset of the increment in $[Ca_i^{++}]$ preceded the onset of O_2^- production. The rise in $[Ca_i^{++}]$ induced by Con A is not transient, with a new, higher steady-state level of $[Ca_i^{++}]$ being attained within five minutes. The addition of α -methylmannoside (α -MM) one minute after Con A resulted in the return of $[Ca_i^{++}]$ to the original baseline level and the cessation of O_2^- production. The addition of a second stimulus (such as arachidonic acid) to these cells resulted in a second increment in $[Ca_i^{++}]$ and the return of O_2^- production. Thus the rise in $[Ca_i^{++}]$ induced by Con A is tightly coupled to the activation, inactivation, and reactivation of the O_2^- generating system by Con A. Further experiments were undertaken to assess the possible requirement for the rise in $[Ca_i^{++}]$ in the activation of PMN by Con A. PMN could be depleted of Ca_i^{++} by loading with Quin2 in the absence of extracellular Ca^{++} . These Ca^{++} -depleted PMN can be induced to produce O_2^- after treat-

ment with PMA but not with Con A. The addition of Ca^{++} to Ca^{++} -depleted PMN results in a return of $[Ca_i^{++}]$ to the normal resting level of Ca^{++} -replete PMN. The time required to return to baseline is a function of the concentration of intracellular Quin2. The addition of Ca^{++} to Ca^{++} -depleted, Con A-treated PMN results in the elevation of $[Ca_i^{++}]$ and the production of O_2^- . Over a tenfold range of intracellular Quin2 concentration, the onset of O_2^- production always occurred at $[Ca_i^{++}]$ that were less than the normal resting level. Thus, activation of the O_2^- generating system by Con A can occur at $[Ca_i^{++}]$ which are much lower than the incremental level induced by Con A in Ca^{++} -replete PMN. Supporting this is the observation that only a very small increment in $[Ca_i^{++}]$ is induced by Con A in PMN cytoplasts, even though Con A could induce O_2^- production in the Quin2-loaded cytoplasts. While a Con A-induced increment in $[Ca_i^{++}]$ is a result of stimulus-response coupling and correlates with the activation of the PMN O_2^- generating system, these observations raise doubts about the necessity of a large change in $[Ca_i^{++}]$ in the activation of the O_2^- generating system.

HUMAN NEUTROPHILS (PMN) respond to various stimuli with the initiation of O_2^- production, secretion of granule contents, chemotaxis, aggregation, or phagocytosis.¹⁻³ Other responses of PMN to stimulation include changes in membrane potential,^{4,5} phosphatidyl inositol metabolism,⁶ protein phosphorylation,^{7,8} membrane-bound calcium,^{9,10} and the concentration of intracellular ionized calcium ($[Ca_i^{++}]$).^{11,12} These latter responses have received much attention because of their potential causal involvement in the activation of PMN.

The use of concanavalin A (Con A) as a stimulant of PMN responses is useful because of the ability of α -methylmannoside (α -MM) to reversibly terminate activation by Con A.¹³⁻¹⁵ In this way the relationships between different PMN responses can be analyzed. For example, when Con A-treated PMN are treated with α -MM, O_2^- production ceases, while granule secretion does not.¹⁵ These PMN are primed for a challenge by an additional stimulus: lag times prior to O_2^- production are shorter, their membrane potential remains depolarized, and they have a diminished requirement for extracellular Ca^{++} for reactivation of O_2^- production by Con A.

Using the trapped Ca^{++} indicator Quin2, we found that Con A induces a sustained rise in Ca_i^{++} that is reversed by the subsequent addition of α -MM. The addition of a second stimulus then results in a second increment of Ca_i^{++} , thus demonstrating that Ca_i^{++} increases every time PMN are activated. We also present data that show that activation of PMN by Con A can occur at levels of Ca_i^{++} that are below the levels obtained after treatment with a stimulus.

MATERIALS AND METHODS

Arachidonic acid, bovine serum albumin, cytochrome c type VI, ethyleneglycol-bis-(β -aminoethyl ether) N,N'-tetra-acetic acid

(EGTA), Ficoll 70, HEPES, lysophosphatidylcholine (LPC), α -MM, p-nitrophenyl β -D-glucuronide, p-nitrophenylphosphate, superoxide dismutase, and triton X-100 were purchased from Sigma Chemical, St Louis; phorbol myristate acetate (PMA) from Consolidated Midland, Brewster, NY; cytochalasin B from Aldrich Chemicals, Milwaukee, WI; Ficoll-Paque and Dextran T-500 from Pharmacia Fine Chemicals, Piscataway, NJ; and the fluorescent calcium indicator Quin2 and Quin2-tetra-acetoxymethyl ester (Quin2 A/M) from Behring Diagnostics, La Jolla, CA. Stock solutions were prepared as follows: Con A at 2 mg/mL in distilled H_2O ; cytochalasin B at 1.0 mg/mL in dimethyl sulfoxide (DMSO); PMA at 2 mg/mL in DMSO and diluted to 20 μ g/mL in buffer for use; and LPC at 2 mg/mL in ethanol. Arachidonic acid was diluted to 2.5 mg/mL in 25% vol/vol ethanol and clarified with 0.1 N NaOH. Quin2 A/M was dissolved at 10 mmol/L in DMSO.

Human peripheral blood PMN were isolated utilizing Dextran T-500 and Ficoll-Paque sedimentation followed by hypotonic lysis of contaminating erythrocytes as previously described.^{16,17} PMN were finally resuspended in phosphate buffered saline (PBS; 135 mmol/L NaCl, 5 mmol/L KCl, 10 mmol/L sodium phosphate buffer, pH 7.40) at 5×10^7 /mL and kept in ice.

PMN cytoplasts were prepared essentially as previously described.¹⁸ PMN at 1×10^8 /mL were incubated in 12.5% (wt/vol) Ficoll 70 containing 20 μ mol/L cytochalasin B for five minutes at 37 °C. These PMN were then centrifuged at $81,000 \times g$ in a Beckman SW-27 rotor at 33 °C for 30 minutes over a prewarmed discontinuous Ficoll gradient of 18% and 25% (wt/vol) Ficoll 70 containing 20 μ mol/L cytochalasin B. The cytoplasts were harvested from the interface between the 12.5% and 18% Ficoll layers. Control PMN (treated at 33 °C in 12.5% Ficoll containing 20 μ mol/L cytochalasin B) and cytoplasts were then washed three times in PBS containing 5 mmol/L glucose and 0.5% BSA and one time in PBS alone before counting and marker analysis. The yield of cytoplasts on a cellular basis was 71% of the PMN layered on the gradient. Depletion of granules in cytoplasts was assessed by measuring the content of β -glucuronidase as previously described.¹⁹ The content of alkaline phosphatase was used as a marker of plasma membrane and was assayed as previously described.¹⁸ Cytoplast β -glucuronidase content was 2% of PMN when normalized per cell and 4% of PMN when normalized per unit of alkaline phosphatase.

O_2^- production was monitored continuously as the superoxide dismutase-inhibitable reduction of cytochrome c as previously described.²⁰ The buffer was Krebs-Ringer Phosphate (KRP; PBS plus 1 mmol/L $CaCl_2$ and 1.3 mmol/L $MgSO_4$) unless stated otherwise. Cytochalasin B (10 μ mol/L) was routinely added to all assays of PMN function, as we find that its presence enhances Con A-induced O_2^- production 20-fold.

Human PMN were loaded with Quin2 A/M essentially as described previously.^{11,21} PMN at 5×10^7 /mL in PBS containing 1.0 mmol/L $CaCl_2$, 5 mmol/L glucose and 0.5% bovine serum albumin were incubated with 50 μ mol/L Quin2 A/M for ten minutes at 37 °C, after which they were diluted to 1×10^7 /mL with the same buffer and the incubation continued for an additional 20 minutes. At that time the PMN were diluted with one volume of cold PBS, centrifuged at 4 °C, washed one time with cold PBS, and resuspended to 5×10^7 /mL PBS. In some experiments the PMN were depleted of Ca_i^{++} by incubation with varying concentrations of Quin2 A/M in the absence of Ca^{++} as previously described.^{22,23} Responses of these PMN were monitored in HEPES-buffered saline (HBS; 135 mmol/L NaCl, 5 mmol/L KCl, 10 mmol/L HEPES, pH 7.40). Where indicated 1 mmol/L $CaCl_2$ was also added.

The fluorescence of Quin2-loaded PMN was monitored essentially as described previously.^{11,21} PMN (5×10^6 in 1.0 mL buffer)

were stirred in the thermostatted (37 °C) sample compartment of a Perkin Elmer 650-10S spectrofluorometer. The excitation wavelength was set at 339 nm (band pass slit of 4 nm), and the emission wavelength was set at 492 nm (band pass slit of 10 nm). The $[Ca_i^{++}]$ was calculated from the maximum fluorescence obtained in PMN lysed with 10 μ g/mL LPC in the presence of 1.0 mmol/L Ca^{++} and the minimum fluorescence of LPC-lysed PMN in the presence of 10 mmol/L EGTA as described previously.²¹ A standard curve of the fluorescence of known amounts of Quin2 in Ca^{++} -containing suspensions of LPC-lysed PMN was also prepared. The fluorescence of lysed Quin2-loaded PMN in the presence of 1.0 mmol/L Ca^{++} was then determined and compared with the standard curve.

PMN and cytoplasts were loaded with chlortetracycline as described by Smolen et al.⁹ PMN at 1×10^7 /mL and cytoplasts at 2.2×10^7 /mL were loaded with 50 μ mol/L chlortetracycline for 20 minutes at 37 °C, after which they were washed by centrifugation and resuspended in PBS. Fluorescence tracings were performed at an excitation wavelength of 380 nm (slit of 6 nm) and an emission wavelength of 560 nm (slit of 6 nm).

RESULTS

Effect of activation of PMN on $[Ca_i^{++}]$. As many reports have recently shown,^{11,12,24} Quin2-loaded PMN can be used to monitor changes in $[Ca_i^{++}]$ induced by various stimuli. Figure 1A shows that Quin2-loaded PMN, pretreated with cytochalasin B (necessary for maximum ConA induced O_2^- production), respond to Con A with an increase in $[Ca_i^{++}]$. The onset of the increment in $[Ca_i^{++}]$ occurs within 15 seconds and precedes the onset of O_2^- production at 30 to 50 seconds. For 12 blood donors, the resting $[Ca_i^{++}]$ for PMN under these conditions is 110 ± 18 nmol/L (mean $\pm$ SD) while that of the peak value of $[Ca_i^{++}]$ induced by Con A is 547 ± 174 nmol/L. After the peak has been achieved there is a subsequent decline in $[Ca_i^{++}]$, which reaches a new steady-state level (a mean of 259 ± 19 nmol/L, $n = 6$) in approximately three minutes. Essentially the same phenomenon occurs when Quin2-loaded PMN are treated with 12.5 μ g/mL arachidonic acid. Figure 1B shows that Quin2-loaded PMN treated with arachidonic acid also undergo a sustained increase in $[Ca_i^{++}]$ that precedes the onset of O_2^- production.

Effect of inactivation of stimulated PMN on $[Ca_i^{++}]$. If the Quin2-loaded PMN are instead treated with 25 mmol/L α -MM one minute after treatment with Con A (at the peak of the $[Ca_i^{++}]$ transient, Fig 2A) the Con A-induced increment in $[Ca_i^{++}]$ is completely reversed and $[Ca_i^{++}]$ returns to its initial, resting level. Treatment of Con A-stimulated PMN with α -MM in this manner results in the cessation of O_2^- production. Thus treatment of PMN with Con A results in a reversible increase in $[Ca_i^{++}]$. In addition, the fluorescence response to Con A appears to be biphasic. The sustained increase in $[Ca_i^{++}]$ induced by Con A is not an artifact due to the Ca^{++} -buffering capacity of Quin2, since the same results are obtained if the PMN are first incubated with Con A and are then loaded with Quin2 (data not shown). In addition, PMN that are treated with Con A followed by α -MM one minute later and are then loaded with Quin2 display the normal resting $[Ca_i^{++}]$. While the time course of changes in $[Ca_i^{++}]$ may be influenced by the buffering capacity of Quin2 as described for FMLP-treated PMN,²⁵ the phenomena are the same whether Quin2-loaded

Fig 1. Effect of Con A and arachidonic acid on $[Ca_i^{++}]$ and O_2^- production. Fluorescence tracing of 5×10^6 PMN/mL KRP that had been loaded with 50 μ mol/L Quin2 A/M as described in "Methods" (upper tracings) and continuous measurement of O_2^- production (lower tracings). (A) The addition of 100 μ g/mL Con A (at the arrow) in the presence of 10 μ mol/L cytochalasin B. (B) The addition of 12.5 μ g/mL arachidonic acid (at the arrow) in the presence of 10 μ mol/L cytochalasin B.

Fig 2. Effect of removal of stimuli on $[Ca_i^{++}]$ and O_2^- production. Fluorescence tracings of Quin2-loaded PMN and O_2^- production as in Fig 1. (A) The addition of 25 mmol/L α -MM (at the second arrow) to Con A-treated PMN. (B) The addition of arachidonic acid (first arrow) followed by the addition of 1.35 mg/mL fatty acid-free bovine serum albumin (BSA) (second arrow).

or control PMN are treated with Con A. In a similar manner, Quin2-loaded PMN treated with arachidonic acid followed by fatty acid-free bovine serum albumin at one minute cease producing O_2^- (as shown in previous reports²⁶⁻²⁸) and undergo a reversal of their increase in $[Ca_i^{++}]$ to their original resting level (Fig 2B).

Effect of reactivation of PMN on $[Ca_i^{++}]$. Previously activated PMN can be reactivated to produce O_2^- by the subsequent addition of another stimulus.^{14,15} As can be seen in Fig 3A, when arachidonic acid is added to PMN previously treated with Con A followed by α -MM, the $[Ca_i^{++}]$ increment is the same as when resting PMN are treated with arachidonic acid (Fig 1B). Figure 3A also shows that arachidonic acid can induce O_2^- production in PMN previously treated with Con A followed by α -MM. PMN that have been activated with arachidonic acid and inactivated with fatty

Fig 3. Effect of second stimuli on $[Ca_i^{++}]$ and O_2^- production. Fluorescence tracings of Quin2-loaded PMN and O_2^- production in the presence of 10 μ mol/L cytochalasin B as in Fig 1. (A) The addition of Con A (first arrow) followed by α -MM (second arrow) followed by arachidonic acid (third arrow). (B) The addition of arachidonic acid (first arrow) followed by BSA (second arrow) followed by Con A (third arrow).

acid-free bovine serum albumin can also be reactivated by the addition of an additional stimulus such as Con A (Fig 3B). The addition of Con A results in an increment in $[Ca_i^{++}]$ and the resumption of O_2^- production. Therefore, for both Con A and arachidonic acid, the increment in $[Ca_i^{++}]$ occurs when PMN are either activated or reactivated to produce O_2^- (Fig 1 and 3), while for both of these stimuli inactivation of the O_2^- generating system by removal of the stimulus also results in the return of $[Ca_i^{++}]$ to the original resting level (Fig 2).

Effect of Con A on cytoplasmic $[Ca_i^{++}]$. The same type of experiment using PMN cytoplasts was performed. Control PMN (5×10^7 /mL, heated to 33 °C for 30 minutes in 12.5% Ficoll/20 μ mol/L cytochalasin B) and cytoplasts (approximately 1.1×10^8 /mL, having the same alkaline phosphatase content as control PMN) were loaded with Quin2 A/M. The resting $[Ca_i^{++}]$ of cytoplasts was 66 ± 3 nmol/L compared to the $[Ca_i^{++}]$ of 151 ± 20 nmol/L for these control PMN (Fig 4). When these Quin2-loaded cytoplasts were treated with Con A, there was a very small increment in $[Ca_i^{++}]$ to 78 nmol/L over several minutes. In contrast, the $[Ca_i^{++}]$ of these control PMN increased to 302 nmol/L after treatment with Con A. Despite the extremely small increment in $[Ca_i^{++}]$ induced by Con A, the Quin2-loaded cytoplasts generated O_2^- at approximately 50% of the rate of control PMN (normalized per unit of alkaline phosphatase, Table 1), with lag times for Con A O_2^- production of approximately 100 seconds. This very small increment in $[Ca_i^{++}]$ of cytoplasts induced by Con A was both inhibitable and reversible with α -MM as was O_2^- production (data not shown). This would indicate that PMN cytoplasts can be activated by Con A to produce O_2^- at levels of $[Ca_i^{++}]$, which are significantly lower than even the normal resting level of PMN. The release of membrane-bound calcium (as measured by following changes in fluorescence of chlortetracycline-loaded cells) was also compared for control PMN and cytoplasts. As shown in Fig 5, the addition of Con A to both PMN and cytoplasts results in a loss of chlortetracycline fluorescence, indicative of a decrease in membrane-associated calcium. In contrast to the Quin2 tracings, the time course of fluorescence change is smaller for both PMN

Fig 4. Fluorescence tracings of cells loaded with 50 μ mol/L Quin2 A/M in KRP. The addition of 100 μ g/mL Con A to 1.1×10^7 cytoplasts/mL in the presence of 10 μ mol/L cytochalasin B. For comparison, the addition of Con A to 5×10^6 control PMN/mL in the presence of 10 μ mol/L cytochalasin B is also shown. The resting and stimulated $[Ca_i^{++}]$ are indicated for both cell types. Comparable results were obtained in each of three separate cytoplast preparations.

Table 1. O_2^- Production by Quin2-Loaded PMN and Cytoplasts

Cells	Stimulus	nmol O_2^- /min/alkaline Phosphatase
PMN	Con A	8.8
PMN	PMA	3.7
PMN	Arachidonic acid	3.5
Cytoplasts	Con A	3.7
Cytoplasts	PMA	1.6
Cytoplasts	Arachidonic acid	2.4

Cytoplasts and control PMN were prepared as described in the text, after which they were loaded with 50 μ mol/L Quin2 A/M. Rates of O_2^- production were then determined for stimulation by 100 μ g/mL Con A, 1 μ g/mL PMA, and 12.5 μ g/mL arachidonic acid in the presence of 10 μ mol/L cytochalasin B. Results are normalized to equivalent amounts of the plasma membrane marker alkaline phosphatase, reported as arbitrary units. Shown are the averages of duplicate determinations (which did not differ by more than 20%) of an experiment performed two times with comparable results.

and cytoplasts and more closely correlates with the lag time for O_2^- production. The ability of PMN to be activated by Con A at low $[Ca_i^{++}]$ was tested by the following experiments.

Studies using Ca^{++} depleted PMN. PMN loaded with Quin2 A/M in the absence of extracellular Ca^{++} can become depleted of $[Ca_i^{++}]$, as previously reported for macrophages and PMN.^{22,23} Therefore PMN were incubated with 10 to 100 μ mol/L Quin2 A/M in the absence of extracellular Ca^{++} , after which they were washed in PBS and resuspended in PBS as usual. The intracellular content of Quin2 was determined as described in the methods section. For these

Fig 5. Fluorescence tracings of chlortetracycline-loaded PMN and cytoplasts. PMN and cytoplasts were loaded with chlortetracycline as described in "Methods." Tracings of fluorescence changes induced by 100 μ g/mL Con A in the presence of 10 μ mol/L cytochalasin B were then obtained for 5×10^6 PMN/mL and 1.1×10^7 mL KRP. A 10% change in initial fluorescence is indicated for each sample, and the absolute fluorescence scale is the same for both tracings. The two tracings are zero-offset by different amounts. Comparable results were obtained in two cytoplast preparations.

PMN the content of Quin2 ranged from 0.2 to 2.0 nmol/ 10^6 cells.

The exact value of $[Ca_i^{++}]$ of Ca^{++} -depleted PMN is difficult to calculate. The fluorescence in PBS of PMN depleted of Ca^{++} with Quin2 was the same as the fluorescence of Quin2-loaded PMN that had been permeabilized with LPC in the presence of 10 mmol/L EGTA. As measured with a Ca^{++} electrode,²⁹ the Ca^{++} concentration of this buffer in the presence of EGTA appears to be less than 20 nmol/L, but the exact value is not known.

In the absence of extracellular Ca^{++} , these PMN were unable to generate O_2^- in response to Con A. However, these PMN were able to generate O_2^- in response to PMA (Table 2), indicating that the PMN were not damaged by depletion of $[Ca_i^{++}]$ as shown previously.²³

The addition of Con A to Ca^{++} -depleted PMN in the absence of additional Ca^{++} does not result in an increase in the indicated $[Ca_i^{++}]$ (Fig 6A). If Ca^{++} is then added to these PMN in the presence of Con A, $[Ca_i^{++}]$ rises and reaches a new steady state level (Fig 6B). The $[Ca_i^{++}]$ of these PMN does not increase further when Con A is added again. In contrast, Ca^{++} -depleted PMN that have been treated first with Ca^{++} followed by Con A do respond with the characteristic stimulus-induced increase in $[Ca_i^{++}]$ (Fig 6C). The time course for the increase in Quin2 fluorescence was a function of the amount of Quin2 found within the PMN (tracings not shown). At all of the concentrations of intracellular Quin2 tested, $[Ca_i^{++}]$ finally returns to the resting level of normal PMN.

These Ca^{++} -depleted PMN were able to generate O_2^- in response to Con A after repletion of $[Ca_i^{++}]$. Figure 7 shows the ability of these Ca^{++} -depleted PMN to generate O_2^- in response to Con A following a ten-minute incubation with Ca^{++} . When $[Ca_i^{++}]$ of these Ca^{++} -depleted PMN is allowed to return to the normal resting level prior to activation with Con A (open symbols in Fig 7), both the lag time prior to O_2^- production and the rate of O_2^- production are close to control values. Thus these PMN can be reversibly depleted of Ca^{++} and can regain their ability to produce O_2^- in response to Con A.

Table 2. Effect of Ca-Depletion on Ability of PMN to Generate O_2^-

Quin2 A/M Incubation	O_2^- Assay	Stimulus	nmol O_2^- /min/ 10^6 PMN
- Ca^{++}	- Ca^{++}	Con A	0
- Ca^{++}	+ Ca^{++}	Con A	3.5 ± 1.7
+ Ca^{++}	- Ca^{++}	Con A	0.1 ± 0.1
+ Ca^{++}	+ Ca^{++}	Con A	6.6 ± 0.4
- Ca^{++}	- Ca^{++}	PMA	6.7 ± 0.8
- Ca^{++}	+ Ca^{++}	PMA	6.4 ± 0.1
+ Ca^{++}	- Ca^{++}	PMA	6.5 ± 0.8
+ Ca^{++}	+ Ca^{++}	PMA	6.4 ± 1.0

PMN were loaded with 50 μ mol/L Quin2 A/M in the presence or absence of 1 mmol/L $CaCl_2$ as indicated. O_2^- production was then measured in the presence or absence of 1 mmol/L $CaCl_2$ and 10 μ mol/L cytochalasin B after a five-minute incubation at 37 $^\circ$ C as indicated. The concentrations of stimuli were: 100 μ g/mL Con A or 1 μ g/mL PMA. Shown are the triplicate values of one experiment (mean $\pm$ SD), repeated two times with comparable results.

Fig 6. Fluorescence tracings of Ca^{++} -depleted PMN loaded with 50 $\mu\text{mol/L}$ Quin2 A/M in the absence of Ca^{++} . (A) The addition of 100 $\mu\text{g/mL}$ Con A to Ca^{++} -depleted PMN in HBS. (B) The addition of 100 $\mu\text{g/mL}$ Con A to Ca^{++} -depleted PMN in HBS followed by the addition of 1 mmol/L CaCl_2 , followed by a second addition of 100 $\mu\text{g/mL}$ Con A. (C) The addition of 1 mmol/L CaCl_2 to Ca^{++} -depleted PMN in HBS. Con A is then added after stabilization of fluorescence. Cytochalasin B (10 $\mu\text{mol/L}$) was present in all samples.

The next study was designed to determine at what $[\text{Ca}_i^{++}]$ the PMN are able to be stimulated with Con A to produce O_2^- . PMN were depleted of Ca^{++} by loading with Quin2 as described above. The PMN were then incubated with Con A for two minutes at 37 $^\circ\text{C}$ in the presence of cytochalasin B. At that time 1 mmol/L Ca^{++} was added, and the lag time

Fig 7. Rate of O_2^- production and lag time by Con A-treated Ca^{++} -depleted PMN in the presence of 10 $\mu\text{mol/L}$ cytochalasin B. PMN were depleted of Ca^{++} by incubation with the indicated concentrations of Quin2 A/M as described in "Methods." O_2^- production was measured in HBS as indicated. Closed symbols indicate PMN that had been repleted with 1 mmol/L CaCl_2 for ten minutes at 37 $^\circ\text{C}$ prior to the addition of Con A. Open symbols indicate PMN that were treated with Con A for two minutes prior to the addition of 1 mmol/L CaCl_2 . Solid lines indicate the rate of O_2^- production. Dashed lines indicate the lag time prior to O_2^- production, which for the solid symbols is calculated from the time of addition of Con A, and for the open symbols is calculated from the time of addition of Ca^{++} .

prior to O_2^- production was measured. As can be seen in Fig 8, when the lag times are compared with the time tracing for the repletion of $[\text{Ca}_i^{++}]$ to these same Ca^{++} -depleted PMN, the lag time for O_2^- production always corresponded to a $[\text{Ca}_i^{++}]$ of approximately 79 nmol/L . This would indicate that activation of the O_2^- generating system by Con A can occur at $[\text{Ca}_i^{++}]$ that is lower than has generally been appreciated.

DISCUSSION

Several laboratories have recently been reporting a phenomenon in PMN termed "priming." In general, priming involves the sequential use of different stimuli, each added at suboptimal concentrations, resulting in a synergistic activation of PMN. For example, PMN treated with low concentrations of PMA followed by FMLP generate O_2^- at a rate far greater than either stimulus alone.^{30,31} This same type of phenomenon has also been reported using PMA and the Ca^{++} ionophore ionomycin.²³

Con A is useful in the study of PMN priming because of the ability of $\alpha\text{-MM}$ to inhibit the binding of Con A to the cell surface. O_2^- production by Con A-treated PMN can therefore be prematurely terminated by the addition of $\alpha\text{-MM}$.¹³⁻¹⁵ While O_2^- production is terminated by this procedure and can be reactivated by an additional stimulus, some other responses are not reversed. The Con A-induced membrane potential depolarization is not reversed and degranulation continues.¹⁵ These cells do not return to a true resting state and appear to be "primed" for reactivation because lag times prior to O_2^- production are shorter in previously activated PMN than for control PMN. In addition, these previously activated PMN have a diminished requirement for extracellular calcium when reactivated with Con A.¹⁵ This led us to speculate that permanent changes in $[\text{Ca}_i^{++}]$ might account for the priming in this system.

Recent reports have utilized the intracellular Ca^{++} indicator Quin2 to monitor changes in phagocyte $[\text{Ca}_i^{++}]$. Using this technique, rapid stimulus-induced increases in $[\text{Ca}_i^{++}]$ are reported for PMN stimulated with chemotactic pep-

Fig 8. Relationship between lag times for O_2^- production with $[\text{Ca}_i^{++}]$ in Ca^{++} -depleted, Con A-treated PMN. PMN was depleted of Ca^{++} as described in "Methods." Fluorescence tracings and O_2^- production lag times were determined in HBS. In all samples 100 $\mu\text{g/mL}$ Con A was added to PMN in the presence of 10 $\mu\text{mol/L}$ cytochalasin B for two minutes followed by the addition of 1 mmol/L CaCl_2 . The arrows for each curve indicate the lag time for O_2^- production for that sample. Shown is a representative experiment. For three experiments, the $[\text{Ca}_i^{++}]$ at which O_2^- production induced by Con A is $79 \pm 20 \text{ nmol/L}$ (mean $\pm$ SD).

tides,^{11,12,24} monocytes²⁹ and PMN^{12,25} stimulated with Con A, and J774 macrophages stimulated with ligands for immunoglobulin Fc receptors.²² An increase in $[Ca_i^{++}]$ is not sufficient to induce O_2^- production by PMN, since elevation of $[Ca_i^{++}]$ with the Ca^{++} ionophore ionomycin does not induce O_2^- production¹¹ and because chemotactic concentrations of FMLP induce a maximal increase in $[Ca_i^{++}]$ but do not induce O_2^- production.^{12,32}

Our data show that the activation of PMN by Con A results in a sustained increase in $[Ca_i^{++}]$ similar to that seen in monocytes²⁹ and in contrast to the transient increase in PMN $[Ca_i^{++}]$ induced by FMLP.^{11,12,24} This sustained increase in $[Ca_i^{++}]$ can be reversed when α -MM is added to Con A-treated PMN. PMN treated in this manner return to the original resting $[Ca_i^{++}]$. These activated and inactivated PMN can then be reactivated by the addition of a second stimulus such as arachidonic acid, resulting in a second increase in $[Ca_i^{++}]$. This result is important because the priming effect seen in PMN treated with Con A followed by α -MM cannot therefore be due to permanent elevations in $[Ca_i^{++}]$. However, these results do confirm that $[Ca_i^{++}]$ is tightly coupled to the activation, inactivation, and reactivation of PMN and that increments in $[Ca_i^{++}]$ occur every time PMN are activated.

We performed the same type of experiment using granule-depleted and enucleated PMN cytoplasts. Cytoplasts activated with Con A to produce O_2^- can be inactivated with α -MM and reactivated with the addition of another stimulus.²⁸ As measured using Quin2, $[Ca_i^{++}]$ of these cytoplasts displayed only a very small increase over several minutes after treatment with Con A. In one previous report, cytoplasts treated with complement fragment C5a did not generate O_2^- or display an increase in $[Ca_i^{++}]$,²⁴ while in another report cytoplasts treated with FMLP did generate O_2^- but displayed only a very small increase in $[Ca_i^{++}]$.³³ The small change in $[Ca_i^{++}]$ in Con A-treated cytoplasts was inhibitable and reversible by α -MM, but the result raised questions about what level of $[Ca_i^{++}]$ is needed for PMN activation by Con A. Although results using chlortetracycline to monitor changes in membrane-associated calcium are difficult to quantitate,^{9,10} it is noteworthy that the time course of fluorescence changes in chlortetracycline-loaded PMN and cytoplasts treated with Con A were similar, and the time course of fluorescence changes of Quin2-loaded cytoplasts in response to Con A were much slower than the changes in control PMN. This raises the possibility that changes in membrane-bound calcium in Con A-treated cytoplasts occur in a time frame consistent with a role in the activation of the cytoplasmic O_2^- generating system. It is also possible that an increment in $[Ca_i^{++}]$ and not an absolute level of $[Ca_i^{++}]$ is the important event in the activation of PMN by Con A.

PMN could be reversibly depleted by $[Ca_i^{++}]$ by loading with Quin2 in the absence of extracellular Ca^{++} . These Ca^{++} -depleted PMN did not generate O_2^- or undergo an increase in $[Ca_i^{++}]$ after treatment with Con A in the absence of extracellular Ca^{++} . The addition of Ca^{++} to these PMN resulted in the return of $[Ca_i^{++}]$ to the original resting level. The rate of the return of $[Ca_i^{++}]$ to resting levels was influenced by the Ca^{++} -buffering action of intracellular

Quin2. This allows the determination of the $[Ca_i^{++}]$ at which O_2^- production begins in response to Con A. Over a tenfold range of intracellular Quin2 concentration, O_2^- production always began at the same $[Ca_i^{++}]$ (approximately 79 nmol/L Ca_i^{++}), which is lower than the resting $[Ca_i^{++}]$ of normal Ca^{++} -replete PMN. This raises the question about whether $[Ca_i^{++}]$ levels above the normal resting $[Ca_i^{++}]$ are needed for activation of PMN by Con A.

Sklar and Oades have also recently reported that Ca^{++} -depleted PMN can generate O_2^- in response to chemotactic peptides at $[Ca_i^{++}]$ that are lower than the normal resting $[Ca_i^{++}]$.³⁴ However, in contrast to our results, they found that increasing rates of O_2^- were obtained with Ca^{++} -depleted PMN that had been repleted to increasing levels of $[Ca_i^{++}]$. Our experiments were possible because Ca^{++} -depleted PMN were absolutely unable to generate O_2^- unless $[Ca_i^{++}]$ had been allowed to increase to a threshold level. Since O_2^- production began at the same indicated $[Ca_i^{++}]$ over a tenfold range of intracellular Quin2, it is likely that all of the PMN were being activated. It is possible that in the studies of Sklar and Oades, using chemotactic peptides, only a fraction of the PMN were generating O_2^- and that these PMN had $[Ca_i^{++}]$ that were higher than the average value obtained in this type of measurement. Another possibility is that the Ca^{++} -dependent transduction mechanisms for Con A and chemotactic peptide stimulation are different, allowing O_2^- to proceed at different $[Ca_i^{++}]$. Supporting this possibility of divergent transduction mechanisms is the report that demonstrates different sensitivity of Con A and chemotactic peptide stimulation to pretreatment of PMN with pertussis toxin.³⁵ These questions will be best answered using the recently developed fluorescent Ca^{++} indicators that are suitable for use in laser-activated flow cytometry.³⁶

It has been reported that PMA-induced activation of PMN protein kinase C can occur at approximately 10 nmol/L $[Ca_i^{++}]$.²³ Thus it appears that some PMN responses can occur at $[Ca_i^{++}]$ that are lower than resting levels, even though increments in $[Ca_i^{++}]$ have been shown to correlate with activation of PMN by all stimuli with the exception of PMA.³⁷ In contrast, it has been reported that granule secretion by PMN that have been permeabilized with either saponin or digitonin is induced by micromolar levels of Ca^{++} .^{38,39} Levels of $[Ca_i^{++}]$ of this magnitude are not required for the activation of Con A-induced O_2^- production by either PMN or cytoplasts. It is still unclear whether stimulus-induced increases in $[Ca_i^{++}]$ are activating events (or promoters of activation) of O_2^- production. It may be that changes in membrane-associated calcium are activating events in PMN and result in an increase in $[Ca_i^{++}]$. Only identification of the PMN components that are either activated or inactivated by calcium will clarify this issue.

ACKNOWLEDGMENT

We are indebted to Drs Sean Scully and George Segel for discussions on the role of intracellular free calcium in phagocytes.

Inactivation of Single-Chain Urokinase (Pro-urokinase) by Thrombin and Thrombin-like Enzymes: Relevance of the Findings to the Interpretation of Fibrin-Binding Experiments

By Victor Gurewich and Ralph Pannell

Whereas crude bovine thrombin activated single-chain urokinase-type plasminogen activator (scu-PA), otherwise called pro-urokinase (pro-UK), purified human thrombin converted pro-UK (scu-PA) to a two-chain form that had no amidolytic activity. The two chains ($M_r \sim 33,000$ and 22,000) were disulfide linked and resistant to subsequent activation by plasmin. By contrast, thrombin did not inactivate tissue plasminogen activator or two-chain urokinase. The enzyme from snake venom *Agkistrodon contortrix*, relatively specific for fibrinopeptide B, had an effect similar to thrombin, whereas the enzyme from *Agkistrodon rhodostoma* (ancrod), specific for fibrinopeptide A, did not. When pro-UK (scu-PA) was present during thrombin clotting of fibrinogen, degradation of ^{125}I -pro-UK (scu-PA) in the clot supernatant was seen, whereas virtually full recovery (95%) of radioactivity was found. A loss of latent

amidolytic activity in the clot supernatant was also found, the extent of which could be correlated with the degree of degradation of the radiolabeled probe. It was concluded that thrombin inactivation of pro-UK (scu-PA) accounts for the loss of amidolytic activity in the clot supernatant, which has been attributed to fibrin binding. Further confirmation was obtained from experiments in which ancrod was used as the clotting agent. Full recovery of both radioactivity and latent amidolytic activity of pro-UK (scu-PA) in the supernatant was obtained under these conditions. These findings indicate that thrombin may introduce an artifact in the results of certain experiments designed to study the fibrin affinity or fibrinolytic effect of pro-UK (scu-PA).

© 1987 by Grune & Stratton, Inc.

WE HAVE PREVIOUSLY REPORTED that, in contrast to the commonly used crude bovine thrombin preparation, Thrombostat (Parke Davis, Avon, CT), purified human thrombin did not activate single-chain urokinase-type plasminogen activator (scu-PA), otherwise called pro-urokinase (pro-UK).¹ A contaminant in the crude bovine thrombin was considered responsible for its effect on pro-UK (scu-PA).

Recently Conforti et al reported that treatment of pro-UK (scu-PA) with purified thrombin inhibited the plasmin activatability of pro-UK (scu-PA).² On more systematic analysis we have found that purified human thrombin and one thrombin-like enzyme from snake venom degrade and inactivate pro-UK (scu-PA) but not tissue plasminogen activator (t-PA) or two-chain urokinase (TC-UK). The relevance of these findings to the interpretation of certain pro-UK/fibrin binding and clot lysis experiments is presented.

EXPERIMENTAL PROCEDURES

Materials. Pro-urokinase (99% single chain), purified from the culture medium of a transformed human kidney cell line was obtained from Collaborative Research, Lexington, MA. High mol wt TC-UK, originating from Green Cross (Osaka, Japan), was obtained as a gift from Dr Bleakley Chandler. Tissue plasminogen activator, predominantly single chain, was obtained from Integrated Genetics (Framingham, MA). Fibrinogen and amidolytic substrate (S-2444) were obtained from Kabi Vitrum (Stockholm, Sweden). Highly purified human thrombin (1623 NIH U/mg) was a gift of Dr John Fenton to Dr Robert Weinstein of this department. Ancrod (from *Agkistrodon rhodostoma* venom) was obtained from Sigma (St. Louis). The thrombin inhibitor N- α -(2-naphthylsulfonyl)-glycyl-D,L-amidinophenylalaninepiperidine (NAPAP) and the thrombin-like enzyme Contortrix, from the venom of *Agkistrodon contortrix*, were obtained from American Diagnostica (Greenwich, CT). Phenylalanyl-prolyl-arginyl-chloromethylketone (PPack) and bovine serum albumin, "Purified" grade, were obtained from Calbiochem (San Diego, CA).

Plasminogen-free fibrinogen was prepared from Kabi fibrinogen by DFP (5 mmol/L) treatment followed by chromatography on Lysine-Sepharose³ equilibrated with 20 mmol/L trisodium citrate, 0.15 mol/L NaCl, and, finally, dialysis against 25 mmol/L HEPES,

pH 7.4, 0.15 mol/L NaCl. The preparation was >99% clottable protein.

Radiolabeling. Pro-UK (scu-PA) and TC-UK were labeled with ^{125}I via the lactoperoxidase reaction using immobilized lactoperoxidase/glucose oxidase (Enzymobeads, BioRad Laboratories) as previously described.⁴ The resulting specific activities were approximately 30 $\mu\text{Ci}/\mu\text{g}$. Labeling was accompanied by some loss of enzymatic activity, but the labeled pro-UK could be fully cleaved by plasmin at a rate comparable to unlabeled pro-UK (scu-PA).

Amidolytic assay of pro-UK (scu-PA) or TC-UK. Amidolytic activity was measured with Kabi substrate S-2444 (0.75 mmol/L) at 37 °C. The reaction buffer was 0.1 mol/L Tris-HCl (pH 8.8), 0.1 mol/L NaCl and 0.1 mg/mL BSA. One enzyme unit (EU) was defined as the amount of enzyme producing a change in absorbance (405 nm) of 1 absorbance unit per minute. Activation of pro-UK (scu-PA) (0.45 $\mu\text{mol/L}$) to TC-UK was accomplished by incubation (37 °C) with plasmin (0.125 $\mu\text{mol/L}$) for 30 to 45 minutes. The amidolytic activity (latent activity) in the mixture was measured with the addition of aprotinin (200 KIU/mL) to the reaction buffer.

Treatment with thrombin or thrombin-like enzymes. The latent amidolytic activity of pro-UK (scu-PA) was measured at intervals after incubation (37 °C) at a concentration of 5,000 IU/mL (50 $\mu\text{g/mL}$) with thrombin (0.01 to 10 NIH U/mL). Similar experiments were carried out with TC-UK (5,000 IU/mL) and with t-PA (50 $\mu\text{g/mL}$).

The effect of the thrombin-like enzymes from *Agkistrodon*

venoms on the amidolytic activity of pro-UK (scu-PA) were also examined in a similar manner: ancred (specific for fibrinopeptide A),⁵ 5 U/mL; and Contortrix (relatively specific for fibrinopeptide B),⁶ 200 mU/mL (chromogenic assay units as defined by the supplier). These concentrations gave clotting times of five to ten minutes under the conditions used in the fibrin clot-binding experiments.

The effect of thrombin inhibitors on the degradation of pro-UK (scu-PA) by thrombin was tested. Thrombin (10 NIH U/mL) was pretreated with PPAck (20 μ mol/L) for one hour at 37 °C. The competitive inhibitor NAPAP was present at 10 μ mol/L during the thrombin treatment of pro-UK (scu-PA). Aprotinin was tested at 500 KIU/mL present during the thrombin treatment.

The fate of pro-UK (scu-PA) during fibrin clot-binding experiments. Fibrin-clot-binding experiments were performed by an extension of the basic method described by Kasai et al.⁷ In brief, pro-UK (scu-PA) or TC-UK (30 to 45 IU/mL) were added to a reaction mixture of plasminogen-free fibrinogen (2 mg/mL), 0.15 mol/L NaCl, 25 mmol/L HEPES (pH 7.4), 0.01% Tween 80, and 0.2% bovine serum albumin. The mixture was clotted with thrombin (1 NIH U/mL, final concentration) or ancred (5 U/mL) and incubated (37 °C) for 15 minutes. The tubes were chilled on ice, vortexed, and centrifuged. The plasminogen activator activity was measured in the supernatant and compared with the activity in tubes without fibrinogen and tubes without thrombin. The average results from five experiments were calculated.

Additional experiments were performed with radiolabeled pro-UK (scu-PA) or TC-UK added to the above mixture. The supernatant and control tubes were analyzed by autoradiography of sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) as well as for radioactivity.

SDS-PAGE. Samples from the above reaction mixtures were subjected to SDS-PAGE by the method of Laemmli⁸ using 10% gels. Samples were prepared with or without 10 mmol/L dithiothreitol and stained with Coomassie brilliant blue G-250 or visualized by autoradiography.

RESULTS

Thrombin inactivation of the latent activity of pro-UK (scu-PA). When pro-UK (scu-PA) was incubated with purified human thrombin, there was a time and thrombin concentration-dependent loss of the latent UK amidolytic activity (generated by subsequent plasmin treatment of the solution) as shown (Fig 1). Pro-UK (scu-PA) was completely protected by NAPAP when it was included in the incubation

Fig 1. Latent amidolytic activity of pro-UK (scu-PA), expressed as percent of baseline enzyme units (EU), recovered after incubation (37 °C) with purified human thrombin (0.01 to 10 NIH U/mL) for 15 (●) and for 60 minutes (○).

mixture; there was only 28% loss of activity when PPAck was used; and aprotinin had no effect on the reaction.

The amidolytic activities of TC-UK and of t-PA were unaffected by incubation with thrombin (10 NIH U/mL for 30 minutes).

Effect of ancred or contortrix venom on the latent amidolytic activity of pro-UK (scu-PA). The latent amidolytic activity of pro-UK (scu-PA) was not affected by incubation (37 °C) with ancred (5 U/mL) for 30 minutes. By contrast, Contortrix venom (200 MU/mL) induced a progressive loss of the latent amidolytic activity of pro-UK (scu-PA), which was comparable to that induced by thrombin. The venom had no effect on the amidolytic activities of TC-UK or t-PA.

Thrombin degradation of pro-UK (scu-PA). A mixture of pro-UK (scu-PA) (5,000 IU or 50 μ g/mL) and thrombin (1 NIH U/mL) sampled at 10, 20, 30, 45 and 60 minutes for SDS-PAGE under reducing conditions, showed progressive degradation of single chain pro-UK (scu-PA) to two chains corresponding to about M_r 33,000 and 22,000. The two chains appeared to migrate just slightly behind the heavy and light chains of the TC-UK marker. A relatively faint higher molecular weight contaminant is also seen (Fig 2).

When the appearance of thrombin-modified pro-UK (scu-PA) under reducing and nonreducing conditions was compared (Fig 3), the thrombin-modified pro-UK (scu-PA) migrated with a M_r of 55,000 under nonreducing conditions (lane 2), indicating that the thrombin cleavage peptides were disulfide linked. The human thrombin appeared as a major and minor band (lane 3) and the pro-UK (scu-PA) as a single band under reducing conditions (lane 1). The higher mol wt contaminant seen in Figure 2 is again seen in the pro-UK-thrombin mixture under reducing conditions (lane 2, Fig 3).

Inactivation and degradation of pro-UK (scu-PA) during fibrin clotting. In the tubes containing buffer, thrombin, and pro-UK (scu-PA), a 49% (mean) loss from control tubes (without thrombin) of the latent amidolytic activity of pro-UK (scu-PA) was found, whereas a 27% (mean) loss was

Fig 2. Reduced SDS-PAGE of M_r 55,000 pro-UK (scu-PA) (50 μ g) incubated (37 °C) with thrombin (1 NIH U/mL) for 0, 10, 20, 30, 45, and 60 minutes. A marker (M) made up of a mixture of pro-UK (scu-PA) and TC-UK is shown. The high mol wt band is a contaminant having no time dependence.

Fig 3. SDS-PAGE under reducing and nonreducing conditions of pro-UK (scu-PA) before (1) and after (2) incubation (37 °C) with thrombin (5 NIH U/mL) for 60 minutes. The human thrombin preparation (5 µg) (3) and a marker (M) made up of a mixture of pro-UK (scu-PA) and TC-UK are shown. A high mol wt band, comparable to the contaminant seen in Fig 2, can be seen in lane 2 (reduced) but not elsewhere.

found in the fibrin clot supernatant. No significant change in the amidolytic activity of TC-UK was observed either in buffer or in the fibrin clot supernatant. A 95% recovery of radioactivity from ^{125}I -pro-UK (scu-PA) and complete recovery of ^{125}I -TC-UK in the clot supernatant were obtained (Table 1).

Autoradiography of SDS-PAGE of incubation mixtures from this experiment showed degradation of ^{125}I -pro-UK (scu-PA) during incubation with thrombin both with and without fibrinogen. Loss of the M_r 55,000-band compared with baseline and appearance of a M_r 33,000-band was seen (Fig 4). The degradation was greater in buffer (lanes 2 and 3) than in the fibrin clot supernatant (lanes 5 and 6). Samples from two experiments with pro-UK are shown to demonstrate the reproducibility of the findings (lanes 2, 3, 5, and 6). There was no change in the appearance of TC-UK (lanes 1 and 4) (Fig 4).

When anacrod (5 U/mL) was used instead of thrombin, there was no loss of either amidolytic activity or radioactivity in the fibrin clot supernatant.

Table 1. Amidolytic Activity and Radioactivity After 15 Minutes Incubation (37 °C) with Thrombin (1 NIH U/mL) or after Thrombin Clotting

	Pro-UK Amidolytic Action Radioactivity		TC-UK Amidolytic Action Radioactivity	
	EU/mL	CPM	EU/mL	CPM
Control	0.98 (100%)	4,175 (100%)	0.110 (100%)	4,015 (100%)
Thrombin + Buffer	0.050 (51%)	4,175 (100%)	0.104 (95%)	4,015 (100%)
Clot Supernatant	0.072 (73%)	3,986 (95%)	0.107 (97%)	4,084 (102%)

Fig 4. Autoradiograph of reduced SDS-PAGE of ^{125}I -pro-UK (scu-PA) (M) after 15 minutes incubation (37 °C) with thrombin (1 NIH U/mL) in buffer (2 and 3) or in fibrinogen solution (clot supernatant) (5 and 6). Samples from two separate clots are shown. The results of similar mixtures with ^{125}I -TC-UK (M1) are seen in lanes 1 and 4 representing buffer and clot supernatant respectively.

DISCUSSION

This study demonstrates that the latent activity of pro-UK (scu-PA) but not the activities of TC-UK or of single chain t-PA, is inactivated progressively by physiologic concentrations of thrombin. Thrombin converted pro-UK (scu-PA) to a two-chain form that had no amidolytic activity.

The two chains generated by thrombin migrated on SDS-PAGE in positions comparable to those of the light and heavy chains of TC-UK. This molecule was not susceptible to activation by plasmin. Conversely, TC-UK was not inactivated by thrombin. The thrombin cleavage site in pro-UK (scu-PA) was close to the plasmin cleavage site within the disulfide-linked domain of the molecule. Inactivation of pro-UK (scu-PA), comparable to that induced by thrombin, was also seen with the thrombin-like snake venom enzyme from Agkistrodon contortrix, relatively specific for fibrinopeptide B, but not with the one from Agkistrodon rhodostoma (anacrod), specific for fibrinopeptide A.

When pro-UK (scu-PA) was incubated with thrombin plus fibrinogen, there was a loss of latent activity in the clot supernatant relative to a buffer control without thrombin. But this loss of activity in the supernatant, previously attributed to fibrin binding,⁸ could be correlated with the degree of degradation seen by SDS-PAGE autoradiography. Further evidence that the pro-UK (scu-PA) did not bind to fibrin under these conditions was the full recovery of both counts from ^{125}I -pro-UK (scu-PA) and plasmin-activatable amidolytic activity in the supernatant when anacrod was used instead of thrombin to clot fibrinogen. Thus in this experimental model, thrombin inactivation of pro-UK (scu-PA) introduces an artifact that may masquerade as fibrin binding.

Conversely, when fibrin affinity is determined by the recovery of UK-antigen after clotting,⁹ degradation of pro-UK (scu-PA) would obscure fibrin binding under experimental conditions in which the fibrin binding of pro-UK itself may occur. The sensitivity of pro-UK (scu-PA) to degrada-

tion by thrombin may also lead to an underestimation of its contribution to lysis when this is studied by measuring spontaneous fibrinolysis after thrombin clotting.¹⁰

The addition of fibrinogen attenuated the inactivation and degradation of pro-UK (scu-PA) by thrombin. This was observed in the fibrin clot-binding experimental model in which the extent of degradation found in the clot supernatant was about 45% less than that in the buffer control. This effect may be explained by competition of the substrate fibrinogen (6 $\mu\text{mol/L}$) with the substrate pro-UK (scu-PA) (9 nmol/L) for the active site of thrombin.

During the finalization of this manuscript, the cleavage of pro-UK (scu-PA) by thrombin at the Arg 156-Phe 157 bond, two residues from the activation site, was identified by Ichinose et al.¹¹ In view of this, it is noteworthy that cleavage at this site renders the Lys 158-Ile 159 bond not susceptible to activation by plasmin. Perhaps not surprisingly, cleavage within the disulfide-linked domain of pro-UK causes a major conformational change in this region, causing the susceptible bonds for plasmin and respectively for thrombin to become nonrecognizable.

This effect of thrombin explains an earlier observation that pro-UK (scu-PA), in contrast to UK or streptokinase, induces little endolysis when incorporated into a forming clot (unpublished), whereas pro-UK (scu-PA) induces exolysis of a preformed clot incubated in plasma very effectively.¹ Physiologically the inactivation of pro-UK (scu-PA) by

thrombin may serve to maintain the integrity of a fresh clot by inhibiting endolysis. Tissue plasminogen activator and TC-UK, though resistant to thrombin, are inhibited by plasminogen activator inhibitor-1,¹² whereas pro-UK is not.¹³ Therefore a separate mechanism appears to exist in a forming clot to inactivate pro-UK (scu-PA) and to prevent the generation of TC-UK.

These findings are relevant to the interpretation of certain published studies but do not resolve the controversy regarding the fibrin binding of pro-UK (scu-PA). They only suggest that pro-UK (scu-PA) does not bind to fibrin under the present experimental conditions. Since a single chain form of UK was first identified in urine and isolated because of its specific binding to fibrin/Celite,¹⁴⁻¹⁶ a certain fibrin affinity for pro-UK (scu-PA) has been assumed. However, this property of pro-UK appears to be conditional, as suggested by the observation of Husain¹⁷ that Zn^{++} is a requirement. We have recently confirmed this Zn^{++} dependence using fibrin-lined tubes pretreated with an antithrombin. Binding of pro-UK (scu-PA) to fibrin/Celite was also confirmed in this study and was shown to be potentiated by Zn^{++} , in contrast to TC-UK, which did not bind and was unaffected by Zn^{++} .¹⁸

In conclusion, the sensitivity of pro-UK (scu-PA) to degradation by thrombin is relevant to the interpretation of some experimental findings and probably is involved in modulating the biologic function of pro-UK (scu-PA).

Large Numbers of Primitive Stem Cells Are Active Simultaneously in Aggregated Embryo Chimeric Mice

By D.E. Harrison, C. Lerner, P.C. Hoppe, G.A. Carlson, and D. Alling

The possibility has been repeatedly raised that erythropoiesis results from clonal succession—the differentiation of one or a very small number of the most primitive stem cells that are sequentially activated to proliferate forming clones of differentiated cells and then eventually decline, to be replaced by new stem cell clones. We studied this possibility in chimeric mice made by combining embryos from two different strains so that they would have two distinct stem cell populations, each of which produces a different hemoglobin type (d and s). These were compared with F_1 hybrids in which every stem cell produces both types. We measured the percentage of type d in seven to ten serial samples of circulating reticulocytes taken at three- to seven-day intervals and found that the variability in percent of this hemoglobin was only slightly higher in the chimeric mice than in F_1 controls; SD ranged from 2.7% to 5.5% in the chimeric mice and from 3.4% to 3.9% in the controls. Using the binomial formula, the numbers of new clones formed during the reticulocyte life span, approximately three days, ranged from 33 to 118 in the individual

chimeric mice. However, these numbers are underestimates because estimated numbers of clones depend inversely on variabilities, and the calculations did not exclude the contribution of experimental error to the overall variability. Total percentages of type d hemoglobin were also measured in seven to nine successive serial samples at 60- to 136-day intervals. These gave mean values similar to measures of newly synthesized hemoglobin in the same mice, but SD were larger, ranging from 5.3% to 8.4%. This reflects experimental error, both because of excess day-to-day variability found in this type of measurement and because there could not be fewer primitive stem cells activated to form clones of erythrocytes during the 45-day erythrocyte life span than during the three-day life span of reticulocytes. Since most and maybe all of the variation between successive samples in the same chimeric mouse appear to result from experimental error, many or even all of the primitive stem cells may simultaneously contribute to erythropoiesis.

THE HYPOTHESIS that normally functioning somatic cells have a limited proliferative capacity¹ appears to be contradicted by findings that long-term repopulating abilities of stem cells are unchanged after a life span of normal function.²⁻⁴ However, only a small fraction of differentiating cells are primitive stem cells, so the kinetic patterns by which they multiply and differentiate have not been defined unambiguously. Important basic information such as the number of stem cells in a marrow graft or the number of doublings that can be achieved by hematopoietic cells cannot be estimated without knowing these patterns. It is possible that most stem cells proliferate very little, so that at any given time only a few contribute to erythropoiesis.⁵⁻¹⁰ This would allow the remaining stem cells to conserve their proliferative capacity.

Numbers of clones contributing to a population made up of two cell types may be estimated using the binomial formula^{8,11} in which the estimated number of clones (n) depends inversely on the variance of the observations (see below). Numbers calculated in this way are underestimates because the variance includes experimental error and is thereby increased so that n is decreased. The estimated number of stem cells is also decreased if any other source of variability within the individual mice is increased. Use of this calculation in our studies is based on the following assumptions: that the different phenotypes in reticulocytes and in mature erythrocytes will occur in the same proportions as those of the active primitive stem cells; that no other mechanisms influence the proportioning of cells of the different genotypes; and that each primitive stem cell becomes inactive after it produces its burst of erythrocytes.

To obtain cells with two distinguishable hemoglobin types, we made chimeric mice by aggregation of early embryos of two distinguishable genotypes. Such mice are normal appearing and may contain cells of both genotypes in any tissue, including the hematopoietic system.¹²⁻¹⁵ Relative pro-

portions of blood cells in such mice may favor one genotype, a tendency that is reduced by using congenic strains.¹⁶⁻¹⁸ Changes with time in populations of RBCs and WBCs and cells in lymphoid tissues within a single mouse have been found in 20% to 60% of chimeras.^{14,19-21} In these "unstable" chimeras, peripheral WBCs and hemoglobin compositions were not correlated.¹⁹ In one set of studies there was no apparent preference for cells of one of the genotypes composing the chimera,²¹ while in a previous report there was a shift to the B6 genotype.¹⁴

Previously reported theories and data implied that very few stem cells produce erythroid cell clones at the same time, and each is active for a short time.⁵⁻¹⁰ If this is true, then much more variability should be observed when newly synthesized rather than total hemoglobin proportions are monitored, since RBCs newly released into the circulation only synthesize hemoglobin for three days and hence are much less subject to the damping effect observed in mature erythrocytes that have overlapping 45-day life spans. The genotypes of both newly released and total RBCs are controlled

by the genotype of the most primitive stem cells from which the blood cells are descended. Therefore we followed changes with time in populations of hemoglobin-synthesizing reticulocytes as well as total RBCs in mice containing cells that produce two distinguishable hemoglobin types.

MATERIALS AND METHODS

Chimeric mice were made from the C57BL/6J (B6) and CBA/HT6J (CBA) inbred strains. B6 and CBA embryos were aggregated at an early preimplantation stage, and the aggregate was allowed to develop to term in a foster mother, using techniques previously described.¹⁵ The B6 and CBA strains have hemoglobin types that are distinguishable by electrophoresis; at the beta chain (Hbb) locus, B6 mice have *Hbb^s* (s, single) hemoglobin, which forms the band migrating farthest on the cellulose acetate gels used, whereas CBA mice have *Hbb-b1^d* and *Hbb-b2^d* (d, diffuse) hemoglobins. These are the intermediate—and slowest—migrating bands, respectively. Only seven of the 24 chimeras consistently had detectable levels of type d bands and were used for these experiments. Coat colors of six of these were roughly equal mixtures of CBA type (agouti) and B6 type (black), while one had only agouti hair. Seven other chimeras with roughly equal mixtures of CBA and B6 coat types produced only B6-type hemoglobin, as did all ten mice with only B6-type coats. There may have been no CBA cells in the latter. All mice were produced and maintained at the Jackson Laboratory, which is fully accredited by the American Association for Accreditation of Laboratory Animal Care.

Reticulocytes in circulating blood cells from these mice were incubated with ³⁵S-labeled methionine to quantitate their hemoglobin synthesis as follows. Peripheral blood was collected from the retro-orbital sinuses, removing 30 μ L in 10 μ L and 20 μ L capillary tubes. The 10 μ L sample was used to determine hemoglobin concentrations to assure that mice did not become anemic with repeated sampling. Hemoglobin synthesizing activity also did not increase with repeated sampling, indicating that reticulocyte numbers did not significantly increase, since only small amounts of blood were used. The 20 μ L sample was added to 100 μ L of F-12M medium (#12-615A, MA Bioproducts, Walkersville, MD) containing 2% fetal calf serum and 50 μ Ci of [³⁵S]-labeled methionine (#SJ-204, Amersham, Arlington Heights, IL) to label freshly synthesized hemoglobin as previously described.^{4,22} Cultures were incubated for three hours at 37 °C in 5% carbon dioxide, balance air.

Hemoglobins were separated by standard electrophoretic procedures as follows: The blood cells were washed twice with cold saline by centrifugation, and the pellet was resuspended in 20 μ L of the Cystamine lysing agent used to prepare hemoglobins for electrophoresis. Samples were frozen to lyse the cells, and the hemoglobin types were separated by electrophoresis on cellulose acetate gels as previously described.^{4,23} These d and s bands are illustrated in Fig 1.

Total amounts of radioactive d and s hemoglobins were determined, and the relative amount of labeled d hemoglobin was expressed as a percent as follows. Each of the hemoglobin-containing bands was cut from the cleared gel, solubilized in 1 mL of Soluene-350 (Packard, #6003038 diluted 9 to 1 with distilled water), and the [³⁵S] activity was counted by scintillation counting with an Omniflor cocktail (#NEF-906B, New England Nuclear, Boston). Background was determined by counting a portion of the gel beyond where the hemoglobin migrated, and background counts were subtracted. Data were expressed as the percentage (counts in diffuse bands/total counts in the diffuse + single bands). Identical separation procedures were used for measurements of total hemoglobins, but packed RBCs were used, and amounts of d and s hemoglobin were determined by densitometry, as previously described.^{4,23}

Two-color analysis by flow cytometry was used to determine

Fig 1. The bands pictured are *Hbb-b1^d* (was *Hbb^{dms}*) and *Hbb-b2^d* (was *Hbb^{dms}*), containing 80% and 20% respectively of the d murine hemoglobin and the s band of s (single or *Hbbs*) hemoglobin. This figure diagrams a typical cellulose acetate electrophoretic gel.

the percentage of *H-2^b/H-2^b* lymphocytes in peripheral blood. Briefly, lymphocytes were isolated from 150 μ L of peripheral blood by centrifugation through Ficoll-Hypaque (LSM, Bionetics Laboratory Products, Kensington, MD) and incubated in 200 μ L with labeled anti-H-2D^b (28-14-8) and anti-H-2K^k (16-3-1) monoclonal antibodies (MoAbs).²⁴ Reciprocal determinations were made using fluoresceinated anti-H-2K^k with biotinylated anti-H-2D^b and biotinylated anti-H-2K^k with fluoresceinated anti-H-2D^b to ensure the accuracy of the results. After washing, binding of the biotinylated antibody was revealed by incubation with phycoerythrin-conjugated avidin (Becton Dickinson, Mountain View, CA). The cells were then analyzed using an Ortho Instruments Model 50H Cytofluorograph with a Model 2140 Data Handling System. Controls included CBA/HT5 and C57BL/6J lymphocytes and a series of different mixtures of the two. Overlap between red and green fluorescence was less than 1%.

RESULTS

Table 1 shows the percentages of ³⁵S-methionine incorporated into hemoglobins newly synthesized by reticulocytes. Seven to ten blood samples were serially tested from each of

Table 1. Newly Synthesized CBA-Type (d-Type) Hemoglobin Percentages in Seven Chimeric and Four F₁ Hybrid Mice

Mouse Type	Identification No.	Percent labeled CBA-type HB*	Calculated No. Clones
Chimeric	1	8.1 ± 2.7 (8)	100
Chimeric	2	8.6 ± 4.1 (7)	47
Chimeric	3	9.9 ± 4.6 (9)	42
Chimeric	4	11.5 ± 5.2 (10)	37
Chimeric	5	9.4 ± 3.8 (9)	58
Chimeric	6	19.1 ± 4.6 (9)	73
Chimeric	7	11.4 ± 5.5 (9)	33
Inbred B6	1a	4.4 ± 4.6 (10)	
F ₁ hybrid	1b	51.1 ± 3.5 (9)	
F ₁ hybrid	2b	51.1 ± 3.9 (6)	
F ₁ hybrid	3b	51.7 ± 3.4 (4)	
F ₁ hybrid	4b	53.9 ± 3.7 (4)	

Chimeric mice were used at 8 to 11 months of age.

*Data given as mean ± SD (n) where n = number of successive blood samples taken from the mouse at three- to eight-day intervals over a 47-day period. One B6 and (B6 × CBA)F₁ control were also used at each of ten intervals, and three more mice of the latter genotype (numbers 2b to 4b) were added part way through the experiment. Random losses of frozen samples caused n = 7 to 10 in the first nine mice of this Table.

seven chimeric mice over a 47-day period at intervals of three to eight days. Also shown are findings in four (B6 × CBA) F_1 hybrid mice and an inbred B6 mouse. In each chimeric mouse the proportion of ^{35}S -labeled d hemoglobin, which represents the corresponding percentage of reticulocytes of the CBA or d phenotype, was low, with mean values ranging from 8.1% to 19.1%. The F_1 hybrids showed close to 50% d hemoglobin as expected, since every reticulocyte in these mice produces hemoglobin of both the d and s types.

In contrast to the wide differences in the mean values of percent d hemoglobin between chimeric and F_1 hybrid mice, there were negligible differences in the corresponding SDs, which in the chimeric mice ranged from 2.7% to 5.5% (average, 4.4%) and in the F_1 hybrids ranged from 3.4% to 3.9% (average 3.6%). A more detailed analysis of the sources of variation was carried out using data collected at seven weekly intervals on the seven chimeric mice. The residual mean square from such an analysis excludes day-to-day variation (which is largely experimental in origin) but not within day experimental error. The corresponding SD was 4.5%, which agrees well with the average of the estimated SDs from the individual mice.

Table 2 summarizes an earlier experiment in which hemoglobin synthesis in reticulocytes from blood samples was serially tested from two chimeric mice 11 times at three-day intervals. The F_1 hybrid and B6 controls were also tested in two and seven of these runs, respectively. Percentages of d hemoglobin in the chimeric mice were low and similar to values found for the same mice three months later (Table 1). As in Table 1, the SDs in chimeric and F_1 hybrid mice were similar.

Table 3 summarizes studies in which total amounts of single and diffuse hemoglobin were serially measured by optical densities (ODs) seven to nine times at successive intervals of 60 to 136 (averaging 100) days, starting at 2 months of age in the same seven chimeric mice used in Table 1. On two occasions systematic variation occurred in the ODs such that zero readings were made for all but one mouse. These data were not used in the calculations. All seven mean values for the percent d hemoglobin were in the same range as those for freshly synthesized hemoglobin shown in Table 1; moreover, there was a moderate positive correlation between mean values obtained in the same mouse by the two assay procedures. (Spearman's $\rho = 0.57$, $p = 0.10$.) The latter finding suggests that experimental error did not obscure the consistency expected in the results of the two

Table 3. Total CBA-Type (d-Type) Hemoglobin Percentages and Other Markers in Chimeric Mice

Mouse No.	Sex	Percent CBA-Type Hb	Coat Color Type	No. CBA-Type Coat/Total Offspring	Percent CBA-Type Lymphocytes
1	M	7.6 ± 5.9 (7)	Mix	10/10	27
2	M	9.2 ± 5.3 (7)	Mix	14/16	2
3	M	7.4 ± 5.8 (7)	Mix	9/9	59
4	F	10.7 ± 6.9 (6)	Mix	1/5	29
5	F	16.2 ± 8.4 (5)	Mix	7/8	—
6	M	20.8 ± 7.3 (6)	CBA	0/0	24
7	M	14.4 ± 5.7 (5)	Mix	0/0	—

Data collections were started on chimeric mice at 8 to 10 weeks of age. Percentages of CBA-type hemoglobins are given as mean ± SD (n) where n = the number of successive blood samples taken from the mouse at 60- to 136-day (mean 100 days) intervals. Coat colors were roughly even mixtures of B6 and CBA types (mix) except in No. 6, whose coat appeared to be only CBA type. Numbers of offspring with CBA-type coat color/total offspring were measured on mating each chimera with a B6 mouse, so that the offspring would have the dominant agouti or CBA color only if this type came from the chimera. Percentages of circulating CBA-type lymphocytes were measured within three days of the last hemoglobin analysis.

assays, especially considering the low range of d hemoglobin values and small number of animals. The SD values shown in Table 3 are appreciably higher than those in Table 1 and are not correlated with the latter (Spearman's $\rho = 0.23$, $p > 0.20$), which suggests that experimental error obscured any possible agreement between a pair of values for the same animals.

Table 3 also shows that six of the chimeras had mixed CBA and B6 coat types, while one had only the CBA-type coat. All or most offspring inherited the CBA-type coat color, indicating CBA germ cells from four of the five chimeras that reproduced when tested. Percentages of CBA-type circulating lymphocytes tested after the final hemoglobin assay were higher than CBA-type (d) hemoglobin in four of five chimeras and much higher in one (Table 3).

DISCUSSION

In the chimeras we studied, the proportion of reticulocytes synthesizing CBA-type hemoglobins was subject to rather low variability that could not be distinguished from experimental error (Tables 1 and 2). The low variability was not due to dependence between values of the successive samples collected, since no systematic increase occurred in the serial correlation coefficients. These averaged -0.10 (range: $-0.43, 0.40$), which is close to the theoretical value (-0.14) associated with complete independence.²⁵ The latter finding is evidence for independence among the sequence of values observed in the individual mice; accordingly, the number of primitive stem cells that had produced reticulocyte clones (n) was estimated using the binominal formula, $n = p(1 - p)/s^2$, where p is the mean proportion of d-type hemoglobin and s^2 is the variance calculated from the series of proportions of d hemoglobin observed in a single mouse. The binomial formula can readily be derived by applying Pearson's method of moments.²⁶ The average of the numbers of primitive stem cells whose progeny actively produced reticulocyte clones

Table 2. Newly Synthesized CBA-Type (d-Type) Hemoglobin Percentages in Two Chimeric and One F_1 Hybrid Mice

Mouse Type	Identification No.	Percent Labeled CBA-Type Hb*	Calculated No. Clones
Chimeric	2	9.1 ± 3.5 (11)	68
Chimeric	4	11.7 ± 3.0 (10)	118
Inbred B6	—	3.1 ± 1.1 (2)	—
F_1 hybrid	—	49.9 ± 2.9 (7)	—

*Two of the chimeric mice described in Table 1 were used three months previously in this experiment. Blood samples were taken at 11 successive three-day intervals. Some of these data were previously published in a different form.⁴

during the three-day reticulocyte life span calculated from data in Table 1 and 2 was 64 (range, 33 to 118). This is far too high for such cells to be serially activated and inactivated, as required by clonal selection hypotheses.⁵⁻⁸

Three simulations were generated as sets of 20 random proportions from binomial distributions with n set at 10, 100, and 1,000 respectively, and $p = 0.116$ (11.6%). The first computer run was used in each case to avoid any selection, with the following results: (mean random proportions expressed as percent $\pm$ SD, estimated number of clones) 11.0 ± 8.5 , 13 clones, 11.9 ± 3.0 , 116 clones, 11.7 ± 1.2 , 717 clones. The SD of ± 3.0 associated with n set at 100 was in the range of the values we found (Tables 1 and 2).

Use of ³⁵S-methionine-labeled hemoglobin not only allowed us to estimate cell production during the short time that a circulating reticulocyte produces hemoglobin but also apparently reduced the day-to-day variability due to experimental error associated with the measurement of optical densities. On seven occasions during the short-term experiments on the chimeric mice, ODs and counts were measured on the same sample. The day-to-day variation in these data, which largely reflects experimental error, amounted to an SD of 7.6 for the ODs compared to only 2.6 for the counts. When total hemoglobins were assayed at intervals longer than mouse erythrocyte life spans, SD values ranged from 5.3 to 8.4 (Table 3). The corresponding numbers of stem cells producing erythrocyte clones estimated using the binomial formula ranged from 19 to 38; these are appreciably smaller than the estimated numbers derived from the reticulocyte data. Since the latter estimates reflect the number of primitive stem cells whose descendants were active over the short reticulocyte life span, it is impossible that they would exceed the corresponding number of stem cells active over the entire life span of the erythrocyte. We infer that experimental error associated with the measurement of ODs accounts for this discrepancy.

Most of the hemoglobin in chimeras made from the B6 and CBA strains was B6 type, consistent with results of Mintz and Palm¹⁴ but not of Warner's group,¹⁹⁻²¹ although in the former study the change to the B6 type occurred over time. Unlike other investigators, we found that the proportion of d hemoglobin in our chimeras was stable or declined only slightly over time. Although variability due to experimental error occurred in both of our assay procedures, it was small enough not to obscure the intrinsic mouse-to-mouse similar-

ity indicated by the correlation between mean proportions of CBA hemoglobin in reticulocytes studied over 47 days (Table 1) and in total hemoglobins studied over about two years in the same mice (Table 3). Consistent with reports by Warner et al,¹⁹ we found more CBA-type cells in lymphocytes than in erythrocytes in four of five chimeras studied. Coat colors were roughly equal mixtures of B6 and CBA types in six and CBA type in one of the chimeras studied, while coat colors in most of the young produced by four of five chimeras were of the CBA type, suggesting a predominance of CBA germ cells (Table 3). Thus proportions of the two types of progenitor cells in the chimeras of this study varied from tissue to tissue, as reported previously,¹²⁻¹⁵ and CBA cells did not grow as well as B6 cells in the erythroid lineage.

The data on variability in reticulocytes suggest that the number of clones active over an erythrocyte life span is at least several hundred, an estimate consistent with other recent data in mice²⁷ and in man.²⁸ These data are contradicted primarily by those of Burton et al,⁸ which have been retracted²⁷; those of Mintz et al,⁹ in which cells were artificially injected into fetal hosts; and those of Lemischka et al,¹⁰ in which descendants of individual stem cells were identified by unique retroviral inserts after transplantation into lethally irradiated recipients. Similar transplantation procedures have been shown to reduce the repopulating abilities of primitive hemopoietic stem cells 10- to 20-fold in adults.^{3,29} By comparison, a life span of normal function, or growth from fetal stages, does not detectably reduce repopulating abilities.^{2-4,29} The relatively large effects of transplantation explain why it may cause erythrocyte production by clonal mechanisms involving sequential activation of later precursors not operating in untransplanted individuals. Our data suggest that the primitive stem cells responsible for long-term erythropoiesis in unmanipulated individuals may not differentiate in terminal bursts but may function continuously. This would be consistent with our finding that the variability of hemoglobin types in repeatedly sampled chimerics was not distinguishable from that due to experimental error.

ACKNOWLEDGMENT

We thank Howard Hoffman for help with the data analysis and Catherine J. Knowles, Michael C. Astle, Joan DeLaittre and Susan Marshall for excellent technical assistance.

Factor XIII A Is Synthesized and Expressed on the Surface of U937 Cells and Alveolar Macrophages

By Richard L. Kradin, Garry W. Lynch, James T. Kurnick, Mark Erikson, Robert B. Colvin, and Jan McDonagh

Factor XIII A subunit was detected in U937 cells and human alveolar macrophages by immunohistology and Western blotting. U937 cells synthesize factor XIII A subunit *de novo* under serum-free, platelet-free conditions, as indicated by ^{35}S -methionine labeling and immunoprecipitation. Thrombin-dependent activity was demonstrated to account for 98% of the total transglutaminase activity in U937 cells ($1.5 \mu\text{g}$ per 0.5×10^6 cells/mL). Intact U937 cells and alveolar macrophages and homogenates from these cells cross-linked fibrin to form γ - γ and α -polymers. Factor XIII A was detected on the surface of intact U937 cells and macro-

phages by flow cytometry and ^{125}I -labeling and immunoprecipitation. Cell surface expression of factor XIII A was augmented in the presence of several soluble macrophage activators; however, no concurrent increase in its biosynthesis was observed. The presence and cell surface expression of factor XIII A subunit within macrophages suggest new pathways by which these cells may function in clotting and in the remodeling of the extracellular matrix during inflammation and wound healing.

© 1987 by Grune & Stratton, Inc.

SUBSTANTIAL EVIDENCE indicates that macrophages participate in extravascular clotting.¹ Macrophages synthesize coagulation factors,² express procoagulant activities,³ bind fibrin to their surface,⁴ and are a source of plasminogen activator.⁵ Factor XIII A subunit has also been demonstrated in monocytes and peritoneal macrophages.^{6,7}

Factor XIIIa catalyzes the formation of a peptide bond between certain γ -carboxamide groups of glutamine and ϵ -amino groups of lysine⁸ on fibrin and other suitable protein substrates. Factor XIII circulates in plasma as a zymogen, composed of two A subunits ($M_r = 75,000$), and two nonenzymatic B subunits ($M_r = 80,000$), with the formula, A_2B_2 .⁹ Intracellular factor XIII has been identified in platelets and megakaryocytes,^{10,11} placenta, and prostate tissue.^{12,13} Within cells, factor XIII is present exclusively as dimers of the A subunit (A_2). The activation of factor XIII requires thrombin and calcium,¹⁴ which convert both intracellular and extracellular zymogens to the same enzyme, factor XIIIa. In contrast with other tissue transglutaminases that do not require activation, factor XIII in cells exists as an enzymatically inactive zymogen.

This paper reports the biosynthesis of factor XIII A subunit in the U937 cell, a human promonocytic tumor line, that shares antigenic and functional phenotypic features with normal macrophages.¹⁵ Both the origin and localization of factor XIII in these cells is described.

MATERIALS AND METHODS

Isolation of factor XIII A and B subunit protein. Placental factor XIII A subunit was purified from Fibrogammin (kindly

provided by Behringwerke AG, Marburg, BRD),¹⁶ and the A_2B_2 and B subunits were purified from plasma as previously described.¹⁷

For electrophoresis and blotting experiments, platelets were isolated from human whole blood, anticoagulated with 3.8% citrate (1/10 vol/vol). Platelet-rich plasma (PRP) was obtained from whole blood via centrifugation at $180 \times g$ for 15 minutes, the pH was adjusted to pH 6.6, PRP was centrifuged at $2,200 \times g$ for 20 minutes, the platelet poor plasma (PPP) was removed, and the platelet pellet was resuspended in citrate buffer, pH 7.5. Following several washes in buffer, the final pellet, free of red blood cells, was resuspended in buffer, pH 7.5, containing 20 mmol/L glucose, 40 mmol/L HEPES, and 20 mmol/L glycine.

PPP was pretreated with blue Sepharose (Pharmacia, Uppsala, Sweden) to remove albumin before precipitation with 40% $(\text{NH}_4)_2\text{SO}_4$. The precipitate was dialyzed extensively against changes of HEPES/glycine buffer, pH 7.5. PRP was treated at 56°C for ten minutes, then removed onto ice for ten minutes, and the heat-denatured fibrinogen was removed by centrifugation.

Erythrocytes were collected from red cell pellets obtained by centrifugation of whole blood at $180 \times g$. The red cell pellet was then washed in several changes of HEPES/glycine buffer pH 7.5 by repeated centrifugation.

Factor XIII-deficient plasma was obtained from a deficient individual prior to transfusion. This plasma contained no detectable factor XIII activity when examined for the incorporation of dansyl-cadaverine into casein¹⁸ or subunit A when examined immunologically.¹⁶

Assay for transglutaminase activity. Factor XIII enzymatic activity was measured by the incorporation of $1,4(n)^3\text{H}$ putrescine dihydrochloride (specific activity = 161 mCi/mg (Amersham Radiochemical Center, Arlington, IL) into Hammerstein casein (Merck, Darmstadt, BRD) as previously described.¹⁹ Nonzymogenic transglutaminase activity was assayed in the absence of thrombin. Disintegrations per minute (dpm) were measured in a β -scintillation counter.

Electrophoresis and electroblotting. Samples for electrophoresis were diluted in an equal volume of reducing (5% dithiothreitol, 8 mol/L urea, 5% sodium dodecyl sulfate [SDS]) or nonreducing (8 mol/L urea, 5% SDS) sample buffer. Samples were boiled for ten minutes, and iodoacetamide (10 mmol/L) was added. The samples were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Electrotransfer of proteins from polyacrylamide to nitrocellulose was performed in a Transphor Electrophoresis Unit, run at 90 V for eight hours.²⁰ BLOTTO solution containing 5% Carnation nonfat dry milk; 0.05% Tween-20; 0.01% Anti-foam A (Sigma Chemicals, St. Louis); 2 mmol/L CaCl_2 ; 0.05% NaN_3 ; and 50 mmol/L Tris, pH 8.0 was used to block active sites on the nitrocellulose paper. Blots were stained with antisera against factor XIII A or factor XIII B (Calbiochem-Behring, La Jolla, CA) for one hour at 18°C . The blots were then washed in

several changes of phosphate buffered saline (PBS) and 0.05% Tween-20 for two hours and stained for one hour with ^{125}I -protein A (New England Nuclear, Boston). After washing, the blots were dried, and autoradiography was performed for variable intervals at -80°C with Kodak X-OMAT-AR film (Eastman Kodak, Rochester, NY).

Crosslinking of fibrin. Fibrinogen was purified from human plasma and iodinated with Na^{125}I by a lactoperoxidase method.²¹ For the fibrin crosslinking experiments, ^{125}I -fibrinogen (1 mg/mL) was crosslinked with purified placental factor XIII (20 $\mu\text{g}/\text{mL}$), CaCl_2 (6 mmol/L), and α -thrombin (10 U/mL) (a gift from Dr John Fenton, NY State Department of Health). U937 cells, U937 cell extracts (2 to 3×10^6), or alveolar macrophages (7.8×10^6 to 1×10^8) were incubated in the presence of ^{125}I -fibrinogen ($\sim 150,000$ cpm/sample), which had been pretreated with p-hydroxymercuribenzoate (PCMB) to inactivate traces of factor XIII in the fibrinogen, and factor XIII deficient plasma, CaCl_2 (20 mmol/L) and human α -thrombin (0 to 10 U/mL) for 60 to 120 minutes at 37°C . Controls of ^{125}I -fibrinogen clotted in a 0, 1/10, or 1/100 dilution of normal plasma in HEPES-glycine buffer were also analyzed. Clots were removed and washed six times in PBS with 1 mmol/L phenylmethylsulfonylfluoride followed by additional washes in HEPES-glycine buffer, pH 7.5. The washed clot was suspended in reducing buffer, dissolved by boiling for ten minutes, and analyzed by 5% or 10% SDS-PAGE. Gels were dried and developed at -80°C for autoradiography as above.

U937 culture and stimulatory conditions. U937 cells were maintained in stationary suspension cultures at a density of 1 to 2×10^5 cells/mL in RPMI 1640 (GIBCO, Grand Island, NY) in the presence of heat-inactivated, 5% fetal bovine serum (FBS) and gentamicin (50 $\mu\text{g}/\text{mL}$) in an atmosphere of 95% air and 5% CO_2 . Cells were stimulated in log-phase growth by recombinant IFN- γ (10 U/mL; Genentech, San Francisco), lipopolysaccharide (LPS; 5 $\mu\text{g}/\text{mL}$), *Escherichia coli*, 026:B6 (Sigma, St. Louis), phytohemagglutinin (PHA; 5 $\mu\text{g}/\text{mL}$; Sigma), or phorbolmyristate (PMA; 20 ng/mL; Sigma) for 72 hours at 37°C in RPMI 1640, 5% FBS and gentamicin.

Monocyte and macrophage preparation. Buffy coats were obtained from 3.8% citrated blood (1/10 vol/vol), collected in siliconized glass tubes. Peripheral blood mononuclear cells (PBM) were separated on Ficoll-Hypaque, washed three times, and resuspended in RPMI 1640 at 2×10^6 cells/mL. PBM were then allowed to adhere to glass for two hours at 37°C prior to washing in warm medium to remove nonadherent cells. Purity was assessed by the ability of adherent cells to phagocytize latex beads (Dow Diagnostics, Indianapolis) and was $>95\%$.

Human bronchioalveolar macrophages were obtained via a 300 mL-saline bronchioalveolar lavage from the right middle lobe of nonsmoking workers who had been exposed to asbestos. These patients had no evidence of lung disease by x-ray or by pulmonary function testing. The lavage was filtered through sterile gauze to remove bronchial mucus, washed and resuspended in RPMI 1640 with 5% FBS and gentamicin, and allowed to adhere to plastic or glass as described above for monocytes.

Immunohistologic staining. Control and stimulated U937 cells were washed free of medium in PBS and assessed for viability by 0.4% trypan blue exclusion. Cells (0.5 to 1.0×10^6) were distributed in polyethylene tubes (Falcon, Oxnard, CA). FcR-IgG on macrophages and U937 cells were blocked with heat-aggregated human IgG (100 $\mu\text{g}/\text{mL}$) (gift of Lynn Baird) for 30 minutes, then washed three times in ice cold PBS containing 0.3% NaN_3 . Cells were pelleted at $400 \times g$ and incubated with saturating concentrations of mouse antihuman monoclonal OKT3, which reacts with all peripheral T cells but not with U937 cells or macrophages; OKM1 (C3bi receptor), which reacts with U937 cells and all macrophages; and

rabbit antihuman factor XIII A and XIII B (Calbiochem-Behringwerke, La Jolla, CA). Cells were then washed with PBS and reacted with F(ab')_2 goat antimouse IgG-FITC (1:40) (Tago, Burlingame, CA) or F(ab')_2 goat antirabbit IgG-FITC (1:40; Cappel Labs, Downingtown, PA). Cells were washed two times in PBS, pelleted and fixed at 18°C with 2% paraformaldehyde, then washed and resuspended in PBS. Cytocentrifuge preparations of macrophages were prepared in PBS, air dried, and stained by an avidin-biotin immunoperoxidase method in a humidified chamber at 18°C . Slides were pretreated with H_2O_2 to inhibit endogenous peroxidase. The slides were incubated with primary antisera for 30 minutes, washed with PBS, and then incubated with biotin-labeled goat antirabbit IgG and avidin-biotin peroxidase complex (Vector Laboratories, Burlingame, CA). They were stained with 3-amino-9-ethyl carbazole and counterstained with hematoxylin.²²

Flow cytometry. Cell surface expression of factor XIII was analyzed with a fluorescence-activated flow cytometer (Spectrum III, Ortho Diagnostic Systems, Westwood, MA) after gating on the desired population utilizing their right and forward angle light scatter characteristics. Viable U937 cells form a cluster on the scatter plot in the same region as T cell blasts. The fluorescence amplifier gains were set at 520 to 600 units. These settings yielded a peak of fluorescence for glutaraldehyde-fixed erythrocytes at channel 100 using a range of 0 to 255 linear units. The median fluorescence intensity was used as a quantitative measure of the amount of binding of antibodies.

Biosynthetic labeling of U937 cells. U937 cells (6×10^6) were washed five times in methionine-free RPMI and plated in 24 well plates at 6×10^5 cells/mL for one hour. $\text{L-}^{35}\text{S}$ -methionine (120 μCi) were added to each well, and the cells were incubated for four hours at 37°C . The cells were washed three times in PBS, with 0.4% NaN_3 at 4°C . The cell pellets were washed in Tris buffer, pH 7.3, centrifuged at $4,000 \times g$, lysed, and extracted in 1 mL of Tris/NP-40 with 1 mmol/L phenylmethylsulfonyl fluoride; lysing was continued on ice in the presence of 3.5 mol/L NaCl. The lysate was precleared with Staph A (New England Enzyme Center, Boston), immunoprecipitated with rabbit antihuman factor XIII A or anti-ovalbumin for 60 minutes at 37°C , and antigen-antibody mixture was incubated with Staph A overnight. The immunoprecipitate was washed in buffer, subjected to three cycles of freezing and thawing, boiled in reducing sample buffer for ten minutes, and analyzed by 10% SDS-PAGE. The resulting gels were dried and developed in cassettes for two to four weeks with Ultrafilm (LKB, Bromma, Sweden).

Surface membrane labeling of U937 cells. U937 cells (1×10^8) were washed four times in PBS with 0.4% NaN_3 and once with 60 mmol/L phosphate buffer. The cells were suspended in 200 μL of phosphate buffer in the presence of 200 μL of lactoperoxidase, Enzymobeads (Bio-Rad, Richmond, CA), 1% beta-D-glucose, and 2 mCi of Na^{125}I for 25 minutes.²³ The reaction was quenched with iced Tris buffer, and the cell pellet was washed four times. Membranes were extracted in the presence of Lysis-EDTA buffer (0.5% SDS; 0.5% Triton; 0.23% DOC; 5 mmol/L EDTA) for 30 minutes on ice. The lysate concentrations were adjusted with 0.5 mol/L NaCl. The lysates were immunoprecipitated with rabbit antihuman factor XIII A antisera, rabbit antihuman XIII B antisera, or anti-ovalbumin IgG; suspended and boiled in reducing buffer; and analyzed on 10% SDS-PAGE. Gels were dried and developed for one to two weeks in cassettes with Kodak-X-Omat film.

RESULTS

Extraction of the factor XIII A subunit from U937 cells. NP-40 extracts from U937 cells were analyzed for factor XIII subunits after SDS-PAGE and electrotransfer

Fig 1. Antifactor XIII A subunit immunoblot of NP-40 extracts of cells. U937 cells (1×10^7 /mL) were extracted in NP-40, analyzed by 5% SDS-PAGE, immunoblotted, and stained with antibody to XIII A and ^{125} I-Protein A. Lane 1: NP-40 extract of U937 cells; lane 2: human IgG (50 μ g); lane 3: $(\text{NH}_4)_2\text{SO}_4$ precipitate of blue-Sepharose absorbed plasma; lane 4: lysate of washed human platelets (600,000/mL); lane 5: washed human red blood cell lysate (10,000/mL); lane 6: purified placental factor XIII A₂ (7.5 μ g/mL); lane 7: thrombin-treated factor XIII A₂ (autoradiograph shows reactivity with both factor XIII A subunit and its activated A' subunit); lane 8: purified A₂B₂ from plasma (15 μ g/mL).

onto nitrocellulose. The presence of factor XIII subunits was detected with monospecific rabbit antisera (Fig 1). A radiolabeled band, with $M_r = 75,000$, was seen to comigrate with purified factor XIII A subunits that had been isolated from plasma, platelet extracts, and placenta. Antifactor XIII A antisera did not crossreact with other proteins (including the B subunit of factor XIII) in plasma, platelet lysates, or U937 cell extracts. Red cell extracts, which lack factor XIII activity but are a rich source of tissue transglutaminase, failed to stain with the antisera, indicating that it did not crossreact with tissue transglutaminase. Placental factor XIII A₂, which had been cleaved by thrombin prior to electrophoresis, was identified as a second radiolabeled band with slightly smaller mol wt ($M_r = 71,000$). These experiments prove the specificity of the antisera for factor XIII A subunit. No staining of the U937 extracts were observed with antifactor XIII B antisera (not shown).

Localization of factor XIII A subunit in macrophages. Factor XIII A antigen was identified in cytocentrifuge preparations of monocytes, macrophages, U937 cells, and platelets with monospecific antisera to factor XIII A (Fig 2). Staining of factor XIII A in monocytes, U937 cells, and platelets was diffuse and homogeneous. Factor XIII A antigen in alveolar macrophages stained with variable intensity, indicating heterogeneous expression of factor XIII A antigen by these cells. Their staining was punctate and appeared to be localized to cytoplasmic organelles. Factor XIII B antigen was not detected within macrophages, platelets, or U937 cells.

To differentiate intracellular and extracellular staining, intact U937 cells and alveolar macrophages were stained in suspension and examined by fluorescence microscopy. Factor

XIII A antigen was localized along the cell surface membrane. Intracytoplasmic staining was not detected. Staining and cytofluorographic analysis of paraformaldehyde-fixed cells confirmed the presence of factor XIII A antigen on the cell surface (Fig 3). To exclude the possibility that surface staining might be due to nonspecific binding by immunoglobulin to inadequately blocked surface Fc receptors, cells were stained with other rabbit antisera, including antifactor XIII B, fibrinogen, and ovalbumin. These control antisera failed to stain the cells as judged by direct visual or cytofluorometric examination. Antifactor XIII A antibodies did not bind to other blood cells, including red cells, lymphocytes, T cell blasts, and polymorphonuclear granulocytes as judged by flow cytometry (not shown). When U937 cells were incubated in the presence of serial dilutions of purified factor XIII A (20 μ g/mL) and antiserum to XIII A, a 40% maximal decrease in the intensity of baseline surface staining for this antigen was observed. However, complete inhibition of staining was not obtained in these experiments. An identical pattern of intracellular and cell surface staining of factor XIII A antigen was observed using mouse antihuman IgM monoclonal antibodies (MoAbs) that were raised against the purified factor XIII A subunit (unpublished observations, G. Lynch and J. McDonagh).

To confirm further the identity of factor XIII A on the U937 cell surface, iodination of factor XIII A and immunoprecipitation by rabbit antibody were performed. This procedure yielded a faint radiolabeled band in the autoradiogram at ~70,000 to 80,000, consistent with the observed relative mobility of factor XIII A subunit under these electrophoretic conditions (Fig 4). This band is not more distinct because factor XIII A antibodies are conformationally dependent; and detergent, which is used for cellular extraction, can interfere with the antigen-antibody reaction. Control rabbit anti-ovalbumin did not precipitate specific radiolabeled bands. Attempts at immunoprecipitating surface factor XIII with MoAbs were unsuccessful, probably because of the IgM nature of these antibodies and conformational dependency of the antigen. Specific cell surface staining of factor XIII A has also been observed in mouse WEHI-3 and J774.2 macrophage cell lines (unpublished results, G. Lynch and J. Oliver).

Synthesis of factor XIII by U937 cells. Biosynthetic labeling of U937 cells and immunoprecipitation were performed in serum-free medium. This produced a distinct band ($M_r = 75,000$) that is consistent with the observed electrophoretic mobility of the factor XIII A subunit (Fig 5). This effectively rules out the possibility that factor XIII A expression by the cells was due exclusively to factor XIII A that had been absorbed to or internalized by macrophages from trace levels in serum. Lanes examined using the immunoprecipitated products of control antisera, ovalbumin, and anti-XIII B (not shown) displayed no specific banding.

Modulation of cell surface factor XIII A on U937 cells. Cells were examined to test if expression of factor XIII A surface-related antigen could be modulated. The intensity of U937 cell surface staining for factor XIII A antigen increased after 48 to 72 hours of incubation in media containing PMA, LPS, or IFN- γ but was unaffected by the

Fig 2. Identification of factor XIII A antigen in U937 cells and macrophages. U937 cells, human alveolar macrophages, blood monocytes, and platelets were prepared on glass slides by cytocentrifugation ($400 \times g$) and stained for both factor XIII A and factor XIII B subunits by an avidin-biotin immunoperoxidase method. Cytoplasmic staining for the factor XIII A subunit is present for: (A) U937 cells, magnification $\times 313$; (B) monocytes and platelets, magnification $\times 200$; (C) alveolar macrophages, magnification $\times 313$. (D) Both monocytes and platelets fail to stain for the factor B subunit, magnification $\times 200$.

presence of PHA or α -thrombin (Table 1). Expression of factor XIII B subunit was not detected under these conditions.

Factor XIII activity in macrophages. Thrombin-dependent factor XIII activity was detected in extracts of U937 cells and alveolar macrophages. Lysates of 0.5×10^6 U937 cells contained $1.4 \pm 0.1 \mu\text{g/mL}$ of thrombin-activatable transglutaminase activity. This represented $\sim 89\%$ of the

total transglutaminase activity of the cells. Thrombin-independent activity in turn accounted for $\sim 10 \pm 4\%$ of the total transglutaminase activity in U937 cells. However, if U937 cells were lysed in the presence of the serine esterase inhibitor, tosylarginylmethyl ester (TAME), thrombin-independent transglutaminase activity was reduced to $> 2\%$ of the total activity.

U937 cells cultured in the presence of $\text{IFN-}\gamma$ (10 to 100

Fig 3. Flow cytometric analysis of U937 cells stained with antibodies to factor XIII A, factor XIII B, and fibrinogen. U937 cells (0.5×10^6) were washed free of medium and incubated with aggregated IgG (100 μ g/mL) before staining with antisera specific for: (A) antifactor XIII A subunit; (B) antifactor XIII B subunit; or (C) antifibrinogen for 30 minutes at 4 °C. Cells were washed and stained with F(ab')₂ goat antirabbit-IgG-FITC. The cells were analyzed on an Ortho Spectrum III cytofluorometer at standardized fluorescent gains. Staining histograms from all three conditions are represented. Vertical axis = cell number; horizontal axis = fluorescence intensity. Note the positive fluorescence for the factor XIII A subunit (filled stars). Curves representing the staining results for factor XIII B subunit and fibrinogen are superimposed (open stars) and failed to stain above the level for the second antibody control [F(ab')₂ goat antirabbit IgG-FITC] alone.

Fig 4. ¹²⁵I surface labeling of U937 and immunoprecipitation of factor XIII A. U937 cells (1×10^6) were labeled with Na¹²⁵I by a solid phase lactoperoxidase technique. The labeled membranes were extracted with detergent, immunoprecipitated with antifactor XIII A and anti-ovalbumin, and analyzed by 10% SDS-PAGE. Lane 1 antihuman ovalbumin; lane 2, antifactor XIII A.

Fig 5. ³⁶S-methionine biosynthetic labeling of U937 cells. U937 cells (6×10^6) were labeled in vitro by ³⁶S-methionine in methionine-free, serum-free media. Supernatants and extracts were precleared with Staphylococcus A and immunoprecipitated. The samples were boiled in reducing sample buffer and analyzed by 10% SDS-PAGE. Autoradiographs of the dried gels were produced on LKB Ultrafilm. Lane 1: mol wt markers; lane 2: antifactor XIII A; lane 3: anti-ovalbumin. Antifactor XIII B was also negative.

U/mL) for 18 to 48 hours showed no measurable increase in cell-related transglutaminase activity, nor was enzymatic activity detected in the external conditioned medium (Table 2). Factor XIII activity in U937 did not increase after similar times in culture in the presence of concanavalin A (Con A), PHA-induced human T cell lymphokine, LPS, and α -thrombin. It appears, therefore, that factors that can increase the surface expression of factor XIII A antigen (Table 1) may not increase the total factor XIII enzymatic

Table 1. Modulation of Surface Expression of Factor XIII A Antigen

Activator/Antigen	T3	Median Fluorescence Intensity		
		C3biR	XIII A	XIII B
Control	23	54	58	45
LPS (5 μ g/mL)	28	61	96	42
PMA (20 ng/mL)	23	92	96	42
IFN- γ (10 U/mL)	24	90	90	43
PHA (5 μ g/mL)	24	78	58	45

U937 cells were maintained in stationary culture at 1 to 2×10^5 cells/mL for 24 to 72 hours in the presence of various activators. Cells were washed, Fc receptors were blocked with aggregated IgG (100 μ g/mL), and stained in suspension by an indirect fluorescence technique. T3 and C3bi receptor antigens were stained with F(ab')₂ goat antimouse IgG-FITC. Factor XIII A and factor XIII B subunits were stained with F(ab')₂ goat antirabbit IgG-FITC. Cell staining, after 72 hours of incubation, was analyzed by flow cytometry. Data represent the median fluorescence intensity of the gated cell population for each condition. Note the increase in expression of factor XIII A antigen after stimulation with LPS, PMA, γ -IFN but not PHA. The C3bi receptor antigen increases with exposure to PMA, γ -IFN, and PHA but is minimally affected by LPS.

Table 2. Transglutaminase Activity of U937 Cells $\pm$ Stimulation by IFN- γ

0.5 $\times$ 10 ⁶ U937 cells/mL	Assay	³ H-Putrescine (dpm)
RPMI	-Thrombin	108 $\pm$ 187
	+Thrombin	1129 $\pm$ 36
IFN- γ	-Thrombin	82 $\pm$ 103
	+Thrombin	1117 $\pm$ 121

U937 cells were grown in serum free RPMI $\pm$ IFN- γ (10 U/mL) for 24 hours. The cells were washed in HEPES-glycine buffer, pH 7.5, resuspended to 0.5 $\times$ 10⁶ cells/mL, and lysed by sonification. Assays were performed in the presence and absence of α -thrombin. Values show the mean and SDs of four separate determinations in disintegrations per minute (dpm) of ³H-putrescine incorporation into casein at pH 7.5.

activity of the cell. Alternatively, increased synthesis of factor XIII A may be offset by its increased intracellular degradation.

Macrophage-induced crosslinking of fibrin. U937 and alveolar macrophage cellular extracts or nonextracted U937 cells and alveolar macrophages incubated in the presence of factor XIII-deficient plasma, PCMB-treated ¹²⁵I-fibrinogen, thrombin, and calcium were capable of producing γ - γ crosslinks and α -polymers in fibrin, but lanes analyzed in the absence of cells or their extracts failed to display crosslinking (Fig 6). Lanes containing cell extracts displayed degradation of the α -chain of fibrin. This phenomenon of α -chain degradation and γ - γ crosslinking has also been observed in systems in which platelets were the only source of factor XIII.²⁴

Intact U937 cells and alveolar macrophages were pretreated with human α -thrombin (0.1 to 10 U/mL), washed, and exposed to PCMB-treated ¹²⁵I-fibrinogen in the presence of calcium, without additional thrombin. Supernatants analyzed by SDS-PAGE revealed the presence of labeled γ - γ dimers. Analysis of the gels by laser densitometry showed a progressive increase (0.5% to 14% of total protein per lane) in γ - γ dimer formation with the concentration of α -thrombin used to treat the intact U937 cells. Similar results were obtained for human alveolar macrophages (data not shown).

DISCUSSION

These studies show that macrophages synthesize factor XIII A subunit *de novo* and are a source of factor XIII activity. With the U937 cell as a model, biosynthesis of factor XIII A occurs in serum-free, platelet-free conditions. Furthermore, macrophage stimulation may be accompanied by translocation of factor XIII A from within the cytoplasm to the cell surface. These findings serve to expand the potential repertoire of macrophages in interactions with the clotting system and in the remodeling of the extracellular matrix that occurs following tissue injury.

Some previous studies have suggested that tissue transglutaminase is the dominant, if not sole source, of transglutaminase activity in macrophages,²⁵⁻²⁷ while other studies find factor XIII in macrophages.^{6,7} One reason for this discrepancy may be that factor XIII zymogen can only be isolated from cells in the presence of EDTA and without reducing conditions. Factor XIII is distinct from tissue transglutaminase by virtue of its immunochemistry, dependence on

Fig 6. Crosslinking of fibrin by U937 cells and alveolar macrophages. Purified PCMB-fibrinogen or fibrinogen in plasma and ¹²⁵I-fibrinogen were clotted with calcium (6 mmol/L) and thrombin (10 U/mL) under varying conditions. The clots were washed, boiled in sample buffer, and analyzed by 10% SDS-PAGE under reduced conditions. Lane 1: fibrin control; lane 2: fibrin and purified placental factor XIII (20 µg/mL); lane 4: fibrin and alveolar macrophage cell lysate (8 $\times$ 10⁶ cells/mL); lane 5: platelet poor plasma; lane 6: 1/10 dilution of platelet poor plasma; lane 7: 1/100 dilution of platelet poor plasma; lane 8: factor XIII-deficient plasma and U937 cell lysate (1 $\times$ 10⁶ /mL). The source of unlabeled fibrinogen was PCMB-fibrinogen in sample lanes 1 to 4 and plasma in lanes 5 to 8. The formation of both γ - γ dimers and α -polymers was observed in the presence of cell extracts without extraneous factor XIII. α -Chain proteolysis (α) was most evident in lanes that contained cell extracts.

thrombin for activation, and its mode of crosslinking fibrin and other substances.^{12,28,29} In this study thrombin-dependent, factor XIII-like activity, assayed in the presence of TAME, accounted for ~98% of the transglutaminase activity within the U937 cell line. This decrease in non-thrombin-related activity in the presence of TAME (from 10% to >2%) may result from the presence of cathepsin-like acid proteases in macrophages, which can activate factor XIII in platelets and are inhibitable by TAME (unpublished observation, G. Lynch). U937 cells are free of surface contamination by platelets. This fact serves effectively to exclude platelets as the source of factor XIII in these experiments and further supports previous observations that factor XIII is present in macrophages.^{6,7}

Factor XIII A antigen was detected on the cell surface membrane of macrophages. Most cysteine metalloenzymes are located within the cytoplasm of cells, making the presence of factor XIII on the surface of macrophages apparently unique. Only translocation of factor XIII A appeared to be affected by macrophage stimulation; factor XIII A secretion was not affected. The expression of cell surface factor XIII A was augmented under conditions that favor expression of other macrophage-associated clotting proteins. LPS is the prime stimulus to the production of procoagulant activity by

macrophages.³⁰ PMA and IFN- γ display a broad array of macrophage activating properties, including promotion of cellular attachment and spreading on most surfaces, superoxide release, cytotoxicity for tumor targets, and increased expression of macrophage fibronectin receptors.³¹⁻³³ Both PMA and IFN- γ promote an increase in the intracytoplasmic concentration of protein kinase-C. PMA has also been shown to produce translocation of intracytoplasmic protein kinase-C into the cell surface membrane.³⁴

Crosslinking of fibrin is a principal role of plasma factor XIII in hemostasis. This is an orderly process that proceeds stepwise via thrombin and calcium-dependent activation of the active site on the factor XIII A subunit and results in the formation of γ and α -crosslinkages with fibrin. This reaction, which occurs readily for fibrin, also takes place at slower rates, when fibrinogen is used as substrate, with α -chain polymerization being faster than γ -chain dimerization.³⁵ With fibrin as a substrate, γ -chain dimers form more rapidly than α -polymers. Crosslinking of fibrin renders the clot highly insoluble and alters the elastic modulus of the clot.³⁶ Also, by covalently incorporating α_2 -plasmin inhibitor into the clot, factor XIII renders fibrin resistant to plasmin-mediated proteolysis.³⁷

In addition to its role in crosslinking fibrin, factor XIII can crosslink several other matrix proteins that are present in vivo in the inflammatory reaction. After fibrin, fibronectin constitutes the next most abundant protein in the plasma clot. Crosslinking of fibrin to fibronectin occurs between the aminoterminal of fibronectin and the α -chain of fibrin.³⁸ Fibronectin can be crosslinked to most types of collagen except type IV.³⁹ Factor XIII also crosslinks fibrin to von Willebrand factor (vWF)⁴⁰ and vWF to collagen.⁴¹ Thrombospondin is a substrate for factor XIII crosslinking.⁴² Gel-solin has recently been shown to be a substrate for factor XIII, and it is also incorporated by crosslinking into plasma clots.⁴³

The potential physiologic consequences of these reactions for macrophages are profound. Macrophages bind fibrin and fibronectin to their surface and secrete thrombospondin.⁴⁴

They display increased adherence and spreading on surfaces coated with fibrin, fibronectin, and collagens. Monocytes increase their expression of Fc and C3b receptors, secrete proteases, interleukin-1, and growth factors following adherence to matrix proteins that are substrates for factor XIII.⁴⁵⁻⁴⁷

The expression of factor XIII represents a potential mode by which macrophages may interact directly with the extracellular matrix. Macrophages and exudative monocytes are likely to provide a local source of factor XIII in inflamed tissues. By stabilizing the extravascular clot to plasmin digestion, factor XIII may favor the persistence of the fibrin network at sites of injury. This clot matrix may provide an attachment site for other macrophages, fibroblasts, and endothelium during inflammation. Clark and Colvin⁴⁵ and Colvin⁴⁸ have shown that fibrin and fibronectin provide a provisional matrix for cell attachment and migration following wounding and prior to the appearance of laminin and Type IV collagen. The capacity of factor XIII to crosslink fibronectin and vWF to fibrin and to collagens suggests that macrophages may play an important role in mediating the order of the remodeling process. A role for macrophages in wound healing is supported by the observation that healing is delayed in their absence.⁴⁹ In addition to suffering from hemorrhagic diatheses and spontaneous abortions, ~14% of factor XIII-deficient individuals display defective wound healing.⁵⁰ However, it is not yet known whether inflammation or the immune response in these patients is altered or whether they are specifically deficient in macrophage-related factor XIII. Clearly, further studies are indicated to define the role of macrophage-associated factor XIII in vivo.

ACKNOWLEDGEMENT

The authors wish to thank Ann Burdeshaw for her expert technical assistance and Dr J Oliver, Department of Pathology, University of New Mexico, for staining the WEHI-31 and J-774.2 cells. We acknowledge the gift of recombinant γ -1 FN from the Genentech Corporation, San Francisco.

Thrombocytopenia Associated With Pregnancy in a Patient With Type IIB von Willebrand's Disease

By Margaret E. Rick, Sybil B. Williams, Ronald A. Sacher, and Laurie P. McKeown

Thrombocytopenia may accompany variant (type IIB) von Willebrand's disease (vWD) and is thought to result from binding of the abnormal von Willebrand factor (vWF) to the patient's platelets with subsequent platelet aggregate formation and clearance. We have studied a patient with type IIB vWD who became thrombocytopenic during two pregnancies. During the third trimester of pregnancy, her platelet counts dropped to 20,000 to 30,000/ μ L, and an increase in the intermediate-sized vWF multimers was seen on agarose gel electrophoresis. During this time her platelet-rich plasma showed spontaneous platelet aggregation, and her plasma caused spontaneous aggregation of normal washed platelets. Antibody to platelet glycoprotein Ib completely blocked the spontaneous platelet aggrega-

tion, while antibody to platelet glycoprotein IIb/IIIa did not block the response at the concentrations used. Inhibitors of platelet function that elevate platelet cyclic AMP also blocked the response, but aspirin had no effect on the spontaneous platelet aggregation. The patient illustrates that the platelet counts in one individual can vary greatly in type IIB vWD and that the thrombocytopenia that occurs can appear under physiologic conditions that stimulate the endogenous production of the patient's abnormal vWF. The mechanisms leading to spontaneous platelet aggregation and thrombocytopenia appear to be similar to those described for other patients with type IIB vWD.

VON WILLEBRAND'S DISEASE (vWD) is an autosomally inherited bleeding disorder in which the von Willebrand factor (vWf) is quantitatively decreased and/or is qualitatively abnormal, leading to defects in platelet-subendothelial interaction and in platelet-platelet interaction.^{1,2} Variant types of vWD have been defined by the presence of an abnormal multimeric structure of the vWf protein and in some types by increased binding of the abnormal vWf to platelets when low concentrations of ristocetin are present. These variants are called type II vWD and are further categorized: in type IIB, the patient's plasma vWf lacks the largest multimers, while the patient's platelets contain the full spectrum of multimers; additionally, the abnormal vWf binds more avidly to platelets in the presence of low concentrations of ristocetin and causes platelet agglutination.^{3,4} Several patients with type IIB vWD have been described who have associated thrombocytopenia, postulated to be a result of in vivo binding of their abnormal vWf to their platelets followed by the spontaneous formation of platelet aggregates and clearance.^{5,6}

We have studied a patient with type IIB vWD during two pregnancies who is unusual because she became thrombocytopenic only during the pregnancies. Investigation of this patient's plasma obtained during the third trimester of pregnancy when she was thrombocytopenic showed that her platelets aggregated spontaneously and that her platelet-poor plasma caused aggregation of normal platelets.

Increased quantities of intermediate and large-sized vWf multimers were also observed on agarose gel electrophoresis of her plasma during this time. These phenomena were not observed before or after the gestational periods. This patient provides insight into the pathophysiology of the thrombocytopenia in type IIB vWD; she represents a IIB variant who becomes thrombocytopenic only during periods of increased production of her abnormal vWf, in this case brought about by the physiologic stimulus of pregnancy. It also demonstrates that nonthrombocytopenic patients with type IIB vWD can produce and release larger multimers of vWf and that these may cause significant thrombocytopenia. The recognition of this syndrome is important because of the difficult clinical management problems associated with it. This patient had marked blood loss during the delivery of her first pregnancy, a stillbirth, and she required Cesarean section and the use of both cryoprecipitate and platelets during her second delivery; she had excessive blood loss in spite of these measures.

CASE REPORT

This 33-year-old white female was initially referred to the National Institutes of Health in 1981 during the ninth month of her pregnancy because of recently discovered thrombocytopenia and a life-long history of bruising. She had recurrent epistaxis during both childhood and adult years, bled with loss of deciduous teeth, and had heavy menstrual bleeding. Her father and paternal grandfather also had a history of life-long epistaxis and easy bruising. The patient's obstetrician had noted thrombocytopenia during the sixth month of her pregnancy but referred her to a hematologist only when the platelet count was noted to drop to <50,000 during the eighth month. A bone marrow aspiration showed normal numbers of megakaryocytes, a presumptive diagnosis of idiopathic thrombocytopenic purpura was made, and the patient was placed on prednisone, 60 mg/d when her platelets dropped to 20,000 to 30,000/ μ L. The patient was referred to NIH for further evaluation because of the lack of response in her platelet count while on prednisone.

Physical examination showed fading ecchymoses on all extremities and findings compatible with a normal pregnancy in the ninth month. The patient's laboratory data are shown in Fig 1 (12/23/81). Spontaneous labor began within one week of the expected date of delivery; although no fetal heart sounds were detected on admission to her private hospital, a prolonged labor was allowed to proceed terminating with the vaginal delivery of a dead fetus on 1/5/82. delivery was complicated by hypertension, a third-degree perineal laceration and subsequent infection, and marked blood loss requiring 65 units of blood products, including RBCs, whole blood, platelets, and cryoprecipitate. The prednisone was slowly discontinued over the next four months, and the patient's platelets gradually returned to normal during that time.

The patient remained stable with normal platelet counts on multiple samples during the next two years (Fig 1). Studies of her vWf and factor VIII (VIII:C) were performed, which confirmed the diagnosis of type IIB vWd (Fig 1). She became pregnant again in the fall of 1984 and had a normal pregnancy except that thrombocytopenia was noted to develop during the second trimester of pregnancy and persisted through the third trimester (Fig 1); spontaneous labor began on April 14, 1985, and a healthy boy was delivered at Georgetown University Hospital by a planned cesarean section. The patient was given both cryoprecipitate and platelets prior to and following delivery but had increased blood loss of approximately 1,800 cc. She recovered uneventfully.

METHODS

The patient gave informed consent for the studies. Blood was obtained by a two-syringe technique using a 19-gauge needle and was placed in 1/100 volume of sodium citrate (10.9 mol/L final concentration). Platelet-poor plasma was obtained by centrifugation at 2,000 g for ten minutes at 4°C; the plasma was used immediately or was frozen in aliquots at -70°C.

Platelet-rich plasma for aggregation studies was obtained by centrifugation of citrated whole blood at 750 g for three minutes at room temperature; the platelet count was adjusted to 200,000/ μ L with platelet-poor plasma (or less as noted in each experiment when the patient was thrombocytopenic; in that case the normal control was adjusted to the same platelet count). Platelet aggregation was completed within two hours using a Chrono-Log Lumi Aggregometer (Chrono-Log, Havertown, PA). Baseline values for light transmission in platelet-rich plasma were adjusted to 5% to 10% on the recorder. Agonists for routine platelet aggregation studies included epinephrine, 7.5 μ mol/L (Parke Davis, Morris Plains, NJ); ADP, 3.8 μ mol/L (Sigma, St. Louis); collagen, 225 μ mol/L (Millipore, Freehold, NJ); and ristocetin, (Lenau, Copenhagen, Denmark). Ristocetin-induced platelet aggregation (RIPA) was tested by adding ristocetin at final concentrations varying from 0.34 to 2.0 mg/mL to 400 μ L of platelet-rich plasma; a normal control was run alternately with the patient sample.

Spontaneous platelet aggregation was assessed by placing 400 μ L platelet-rich plasma in an aggregometer cuvette, stirring at 900 rpm and following the change in light transmission for 15 minutes; control platelet-rich plasma prepared in parallel was alternated with the patient's sample during the testing. When antibodies (purified

IgG) or inhibitors were used in the platelet aggregation studies, they were added to the platelet-rich plasma three minutes before addition of the stir bar (except P-PACK, which was added ten minutes before). Two monoclonal antibodies (MoAbs) were used, both the gift of Dr Barry Coller: 6D1 directed against platelet glycoprotein Ib (GP Ib) (9.8 μ g/mL final concentration), and 10E5 directed against platelet glycoprotein IIb/IIIa (GP IIb/IIIa) (1 to 16 μ g/mL final concentration). The inhibitors included PGI₂, 24 μ g/mL (Sigma Chemical); db cAMP, 9.1 mmol/L (Sigma); acetyl salicylic acid (ASA), 0.45 μ g/mL (Aldrich Chemical, Milwaukee); and D-phenylalanyl-L-phenylalanyl-L-arginine chloromethyl ketone (P-PACK), 10⁻⁶ mol/L (Calbiochem-Behring, LaJolla, CA), all given as final concentrations.

Mixing studies were performed using platelets that were separated from plasma proteins by arabinogalactan gradient centrifugation as previously reported.⁷ Platelets from a normal subject who had not taken medications for two weeks and platelets from the patient were prepared simultaneously. In these experiments the separated platelets and platelet-poor plasma were mixed in the cuvette to a final concentration of 200,000 platelets/ μ L in a total of 0.4 mL volume. Spontaneous platelet aggregation was assessed as noted above. In instances where an inhibitor or antibody was added, the separated platelets and platelet-poor plasma were placed in the cuvette and the inhibitor added immediately and incubated for three minutes before stirring and platelet aggregation.

VIII:C, vWf antigen (vWf:Ag) and ristocetin cofactor assays were performed as previously reported.^{8,9} One unit of activity or antigen is that present in 1 mL of pooled normal plasma for each assay. Glyoxyl agarose gel electrophoresis was performed according to the method of Hoyer and Shainoff.¹⁰

Bleeding times were performed by the Mielke et al template method.¹¹

RESULTS

Coagulation studies. When initially seen during the ninth month of her first pregnancy, the patient was thrombocytopenic and had a prolonged bleeding time of 19 minutes (Fig 1). Her factor VIII and vWf values were within the normal laboratory ranges (nonpregnant population), but her vWf multimer pattern showed a decrease in the largest multimers (Fig 1: 12/23/81). After recovery from the traumatic delivery and perineal infection, the patient's platelet count rose to the normal range and her factor VIII and vWf values fell to abnormal levels; the vWf multimer pattern became more distinctly abnormal, with an overall decrease in quantity and fewer large forms present (Fig 1: 8/82 to 8/83). During her second pregnancy, decreased platelet counts, increased factor VIII and vWf values, and vWf multimer patterns similar to those seen in the first pregnancy were observed (Fig 1: 1/29/85 to 4/14/85); these values returned to the patient's baseline levels within approximately one month after delivery.

Platelet aggregation studies. Routine platelet aggregation studies performed when the patient was not pregnant and when her platelet count was in the normal range showed normal aggregation responses and release of ATP to epinephrine, ADP, and collagen. Ristocetin-induced platelet aggregation revealed that the patient's platelets responded to 0.34 mg/mL of ristocetin, while control platelet-rich plasma required >0.87 mg/mL to elicit an aggregation response (Table 1). No spontaneous platelet aggregation was observed when the patient was not pregnant.

Table 1. RIPA: Initial Slopes of Patient and Control at Varying Ristocetin Concentrations

Ristocetin (mg/mL)	Patient (mm/min)	*Control (mm/min)
1.30	40	47
0.87	31	3
0.52	14	0
0.34	8	0

Platelet-rich plasma from patient and control (200,000/ μ L) were run alternately using the concentrations of ristocetin noted.

*Average for PRP from six normal subjects: 0.34 mg/mL, 0 mm/min; 0.5 mg/mL, 4 mm/min; 1.0 mg/mL, 10 mm/min; 2.0 mg/mL, 62 mm/min.

Special platelet aggregation studies. Studies performed during the third trimester of the patient's second pregnancy demonstrated that the patient's platelets aggregated spontaneously (Fig 2, panel A). This spontaneous aggregation was inhibited by the MoAb to GP Ib; however, the antibody to GP IIb/IIIa did not inhibit aggregation (Fig 2, panels B and C).

Mixing studies using platelet-poor plasma and platelets separated from plasma proteins indicated that the patient's plasma rather than her platelets was responsible for the spontaneous platelet aggregation. Patient plasma added to normal platelets showed a spontaneous aggregation response (Fig 2, panel D), while normal plasma added to patient platelets showed no spontaneous aggregation. The aggrega-

tion response observed with patient plasma and normal platelets could be inhibited by the antibody to GP Ib but could not be inhibited by the antibody to GP IIb/IIIa, similar to that seen with patient platelet-rich plasma.

The addition of various inhibitors to the patient's platelet-rich plasma revealed no inhibitory action of ASA; however, PGI₂ caused disaggregation of an early small aggregation response, and the thrombin inhibitor P-PACK abolished the spontaneous aggregation. Prostaglandin I₂ and dibutyryl cyclic AMP also inhibited the spontaneous aggregation in the mixture of patient plasma and normal platelets (data not shown).

Studies performed four months after the successful termination of her second pregnancy showed that the patient no longer demonstrated spontaneous platelet aggregation. Ristocetin-induced platelet aggregation (1.3 mg/mL) of patient platelet-rich plasma was completely abolished by preincubation with the anti-GP Ib but not by the anti GP-IIb/IIIa, similar to that seen with normal platelet-rich plasma. The patient, but not the control, aggregated when ristocetin was added at a final concentration of 0.87 mg/mL; the anti-GP IIb/IIIa abolished this aggregation response. This antibody also prevented aggregation of patient platelets when ADP (5, 10, and 25 μ mol/L) was added.

DISCUSSION

Recent studies have indicated that the abnormal vWf of patients with type IIB vWd binds to the platelet membrane receptor GP Ib in the absence of ristocetin. This binding apparently stimulates exposure of the platelet membrane receptor for fibrinogen, GP IIb/IIIa, making it available to plasma fibrinogen, which binds and initiates aggregation.^{5,12} The platelet aggregates are then thought to be cleared *in vivo* by normal clearance processes. Although the majority of patients with type IIB vWd do not have thrombocytopenia, a number of patients have been reported with low platelet counts.^{5,6} Thrombocytopenia has also occurred in type IIB patients after therapeutic infusion of desmopressin (DDAVP), which transiently elevates levels of vWf in the circulation, including the largest multimers, making them available to bind to platelets.¹³

The production of an abnormal vWf in our patient was physiologically stimulated during pregnancy, and the levels rose into the "normal" range; larger multimers than had been previously noted were also observed. Both the qualitative and quantitative changes in the abnormal vWf led to spontaneous platelet aggregation and thrombocytopenia, likely by the mechanism outlined above. Although this same phenomenon may occur when the patient is not pregnant, it appears that the concentration of abnormal vWf is not sufficient to lead to enough platelet aggregation *in vivo* to cause thrombocytopenia. The levels of abnormal vWf and the larger multimers in particular are clearly important in the clinical manifestation of thrombocytopenia.

Antibodies to GP Ib completely inhibited the spontaneous aggregation in our patient, similar to previous studies.^{5,12} The anti-GP IIb/IIIa did not inhibit the aggregation, however. Since this concentration of anti-GP IIb/IIIa did prevent the exaggerated response to ristocetin (0.87 mg/mL) and pre-

Fig 2. Spontaneous platelet aggregation: panel A, spontaneous platelet aggregation of patient's platelet-rich plasma with normal platelet-rich plasma control; panels B and C, inhibition of spontaneous platelet aggregation in patient's platelet-rich plasma by anti-GP Ib (panel C) and lack of inhibition by anti-GP IIb/IIIa (panel B); panel D, spontaneous platelet aggregation of isolated normal platelets induced by patient's plasma.

vented ADP-induced platelet aggregation four months after delivery, there may have been another mechanism (not related to GP IIB/IIIa) mediating part of the spontaneous platelet aggregation during pregnancy. Alternatively, the lack of inhibition by anti-GP IIB/IIIa may be related to the quantity of the antibody required to prevent exposure of the fibrinogen binding site during pregnancy in this patient despite the fact that this quantity of 10E5 has prevented spontaneous platelet aggregation in several other (nonpregnant) type IIB patients.⁵

The spontaneous platelet aggregation in this patient was inhibited by agents that increase platelet levels of cyclic AMP (PGI₂ and db cAMP) but was not inhibited by aspirin, indicating that the aggregation is not dependent on prostaglandin metabolism. This pattern of inhibition has been observed previously in patients with type IIB vWd.⁵ The inhibition by P-PACK suggests that generation of small amounts of thrombin may have contributed to the exposure of fibrinogen binding sites in this patient; however, hirudin did not show any inhibitory effect in this patient's spontaneous platelet aggregation (data not shown), so the mechanism of action of P-PACK in this setting is not clear.

This patient demonstrates that there can be a wide spectrum of platelet counts and variable decreases in the larger vWf multimers within one patient with type IIB vWD, depending on the physiologic conditions. The patient further

suggests that the presence or absence of thrombocytopenia is related to the level of circulating endogenous larger vWf multimers. A family recently reported¹⁴ with a normal baseline vWf multimer pattern on agarose gels and increased RIPA at low concentrations of ristocetin may also represent part of this spectrum. In that family, the addition of low concentrations of ristocetin to the patients' PRP caused binding of the largest vWf multimers, resulting in a residual type IIB multimer pattern. While the molecular defect(s) is unknown in type IIB vWd patients and in this family, it seems likely that the defect(s) leads to an increased ability of the abnormal vWf to bind to GP Ib.

Clinical evaluation of pregnant patients who present with thrombocytopenia should include a careful questioning about life-long bleeding problems and any family history of excessive bleeding; if the history is positive, evaluation of the patient's vWf, including multimer studies, should be carried out. The clinical management of pregnancy in patients with type IIB vWD requires close clinical and laboratory supervision and conservative treatment with cryoprecipitate and platelets.

ACKNOWLEDGMENT

We thank Dr Harvey R. Gralnick for helpful discussions, Dr Barry Collier for the monoclonal antibodies, and Lynda Ray and Laina Pack for preparation of the manuscript.

Initial Experience in Treating Human Lymphoma With a Chimeric Univalent Derivative of Monoclonal Anti-idiotypic Antibody

By T.J. Hamblin, A.R. Cattan, M.J. Glennie, M.R. MacKenzie, F.K. Stevenson, H.F. Watts, and G.T. Stevenson

Murine monoclonal anti-idiotypic antibody was raised against the surface IgM on the neoplastic cells of a patient with widespread follicular lymphoma. For therapy, a chimeric antibody derivative, FabIgG, was constructed by thioether-linking Fab γ , from the monoclonal antibody, to human normal IgG. FabIgG is univalent and thereby avoids rapid antigenic modulation. Its human IgG component is intended to optimize recruitment of effectors and metabolic survival while minimizing immunogenicity. Four intravenous (IV) infusions of 380 to 580 mg of anti-idiotypic FabIgG were given over a period of 11 weeks. There was no significant toxicity. On each occasion, the antibody disappeared from the plasma with a half-life ($t_{1/2}$) of <24 hours. The brief survival was evidently due to uptake by tumor, as infused control FabIgG, containing Fab γ from an

irrelevant antibody, yielded a plasma $t_{1/2}$ of >10 days. With each therapeutic infusion, there was a fall in the number of circulating neoplastic cells over a 24-hour period. The numbers were largely replenished over the next week, but a net fall became discernible over the entire period of treatment. Four days after each infusion, nodal masses were swollen and tender, subsiding over ~8 days. At the end of the treatments, the blood lymphocyte count and nodal and splenic swellings continued to subside, so that by 6 weeks a partial remission with removal of >50% of tumor was judged to have occurred. We did not detect any qualitative change in surface idiotype nor any antibody response to the infused Ig.

THE TREATMENT OF lymphoid malignancies with antibody has to date yielded quite modest results, with most patients showing only partial or transient remissions.¹ Included in this experience is the use of anti-idiotypic antibody (anti-Id) directed against variable regions of tumor surface immunoglobulin (Ig).²⁻⁷ The target represents a uniquely well-characterized differentiation antigen, of specificity so narrow that at present an individual anti-Id must be raised for each tumor to be attacked.⁸ Monoclonal technology has improved therapeutic prospects by making anti-Id available as a homogeneous reagent in indefinitely large quantities but, despite initial promise,⁴ its inherent antitumor effect is unlikely to be better than that of earlier polyclonal reagents when given in unmodified form.

Factors limiting the therapeutic efficacy of anti-Id are by no means fully defined.^{1,8} They probably include sparse surface Ig, an appreciable secretion of the tumor Ig, idiotypic heterogeneity within a tumor, antigenic modulation, the failure of antibody to recruit appropriate effectors (the roles of complement and the various cellular effectors are poorly understood), and induction of an anti-antibody immune response. Some of these factors can be taken into account when cases suitable for therapy are selected, and some can be by designing suitable derivatives of antibody. For example,

experience has emphasized the difficulties involved in treating with anti-Id those lymphomas secreting appreciable idiotypic Ig into extracellular fluid⁶; we showed in animal lymphoma that certain univalent antibody derivatives, which avoid antigenic modulation, are therapeutically superior to the bivalent parent antibodies.^{9,10}

In this article, we present initial data on the therapeutic use in humans of an antibody derivative designed to avoid or minimize several of the above problems. The derivative is the chimeric univalent antibody, FabIgG (Fig 1). It consists of Fab γ from mouse monoclonal anti-Id, linked by tandem thioether bonds to human normal IgG. Preparation and preliminary characterization of FabIgG have been described.¹¹ Being univalent, it avoids rapid antigenic modulation.^{12,13} The possession of a human Fc γ region, within the IgG moiety, is designed to optimize recruitment of effectors, prolong the metabolic half-life ($t_{1/2}$),¹⁴ and minimize immunogenicity.¹¹ The first patient to be treated has undergone a partial remission of lymphoma and yielded data supporting the above contentions.

MATERIALS AND METHODS

Patient. B.R., a white woman, was seen in October 1983 at the age of 51 for a lump in the left axilla which on excision biopsy proved to be non-Hodgkin's lymphoma (centroblastic/centrocytic, nodular). No other lymphadenopathy was detected, but her spleen was palpable on inspiration. The blood showed hemoglobin (Hb) 13.3 g/dL, WBC count was $14.2 \times 10^9/L$, and platelet level was $225 \times 10^9/L$. The differential count was neutrophils 49%, lymphocytes 47%, and monocytes 4%; among the lymphocytes, small cleaved cells and centroblasts were prominent. Marrow aspirate revealed increased numbers of small cleaved lymphocytes, and paratrabecular infiltrates of lymphoma were seen on a trephine sample. Serum Ig levels were normal. Urinary Ig comprised κ 1.3 mg and λ 1.9 mg/24 hours; no clear evidence of a monoclonal component was seen on immunofixation of an isoelectric focusing pattern from concentrated urine. A lymphangiogram revealed enlarged nodes with abnormal patterns in paraaortic, parailiac, and inguinal regions. Studies of lymphocytic surface markers are summarized in Table 1. Blood lymphocytes stimulated with phorbol ester and pokeweed mitogen (PWM) showed Trisomy-12 on karyotyping. Leukapheresis in November 1983 yielded $\sim 10^{10}$ lymphocytes after separation over

Fig 1. FabIgG prepared from the Fab'Y fragment of mouse monoclonal anti-idiotype antibody (anti-Id) and human normal IgG. Two thioether bonds link the two components through a phenylene ring. Attachment to Fab'Y is probably at a hinge 1/2-cystine as shown. Attachment to IgG has a high probability of being at one of the interchain 1/2-cystines, but is not known to show any preference among them. Residual interchain disulfide bonds are indicated by narrow lines.

Lymphoprep (Nyegaard, Oslo). These were used for studies in vitro and to derive tumor Ig for immunization.

The patient remained asymptomatic and was observed without treatment. In January 1985, examination revealed a splenic edge 4 cm below the costal margin and enlarged mobile lymph nodes as follows: left axilla 2×2 cm; left submandibular, two adjacent together 4.5×2 cm; left inguinal, two groups 4×1 and 2×2 cm; and right inguinal 1×1 cm. The leukemic overspill had not increased commensurately: WBC count was $11.2 \times 10^9/L$, lymphocytes 69%.

We decided to see whether the patient's tumor burden could usefully be reduced by antibody before resorting to conventional chemotherapy. Informed consent was obtained from the patient, and ethical clearance was granted by the East Dorset District Health Authority Research and Ethical Committee.

Marker studies. Blood lymphocytes and dispersed cells from the excised lymph node were prepared as described previously.¹⁵ The blood was drawn into preservative-free heparin. A portion of lymph node was minced and teased in Eagle's minimal essential medium (MEM) containing preservative-free heparin (20 U/mL), and rinsed through nylon gauze. Cells from both sources were then treated similarly. After separation over Lymphoprep, they were washed three times with 2% bovine serum albumin (BSA) in phosphate-buffered saline (PBS). Before being stained, they were incubated for 60 minutes at 37 °C in BSA (2%)-MEM to remove

extrinsic Ig bound to Fc receptors. Sources of monoclonal antibodies were as follows: UCHT1, University College Hospital, London; RFA1, Royal Free Hospital, London; J5, Coulter Electronics, Luton, England; FMC4 and FMC7, SeraLab, Crawley Down, Sussex, England. Rabbit polyclonal anti-Ig reagents were visualized by direct immunofluorescence, UCHT1 and FMC4 by immunoperoxidase technique, and the other monoclonal antibodies by indirect immunofluorescence. Percentages of cells forming rosettes with sheep erythrocytes were determined as described previously.¹⁵

Ig for immunization. Idiotypic IgM λ as a source of immunogen was "rescued" for secretion in culture by fusing the patient's tumor cells with the mouse myeloma line 653. This technique yields a xenohybridoma that secretes Ig derived from the human tumor.¹⁶ For fusion, disaggregated cells from the patient and myeloma cells were mixed at a ratio of 2:1 in polyethylene glycol (PEG) 4000 (Merck-Schuchardt, Munich), washed in Dulbecco's MEM (DMEM) (GIBCO). Then, while still clumped from fusion, the cells were incubated at 37 °C for 2 to 4 hours in the DMEM containing 20% fetal calf serum (FCS); 2 mmol/L of L-glutamine; 1 mmol/L of sodium pyruvate, penicillin, and streptomycin both at 100 IU/mL; and HAT (10^{-4} mol/L of hypoxanthine, 4×10^{-7} mol/L of aminopterin, and 1.6×10^{-5} mol/L of thymidine). Finally, the cells were suspended and distributed into wells of a 96-well microculture plate (GIBCO, Paisley, Scotland), at $\sim 2 \times 10^5$ patient cells per well on a feeder layer of washed mouse blood cells. Colonies were screened by enzyme-linked immunosorbent assay (ELISA) for production of human IgM. Positive colonies were cloned at regular intervals by limiting dilution to guard against spontaneous loss of Ig chain production.

Monoclonal anti-Id. Xenohybridoma culture supernatant containing rescued idiotypic IgM was used as a source of immunogen for the immunization of Balb/c mice (Avonvale, Ashley Heath, England). The idiotypic 19S IgM was given in the form of purified immune complexes formed using mouse anti-human Fab μ serum by the method we described previously for the production of sheep polyclonal anti-Id serum.¹⁵ Each animal received complexes containing 10 to 50 μ g idiotypic IgM in 0.2 mL of complete Freund's adjuvant (CFA, Difco), distributed among four subcutaneous (SC) sites along the back. Two weeks later, animals were boosted by intravenous (IV) injection of a similar antigen dose in 0.2 mL of aqueous medium. Immune splenic lymphocytes were prepared 3 to 4 days later for fusion with the mouse myeloma line 653 by the method described for rescue of idiotypic IgM. Supernatants from the resulting hybridoma cells were assessed for reactivity with idiotypic IgM and normal human IgM by double-determinant ELISA.^{17,18} Those showing strong reactivity with the former but none with the latter were assessed further for reaction with the patient's tumor cells by indirect immunofluorescence, both with and without pooled normal human serum.¹⁸ (Reactivity not blocked by the normal serum can only be directed against highly private idiotypic determinants.⁸)

Suitable anti-Id-producing cells were cloned by limiting dilution and then expanded for large-scale antibody production in pristane-primed Balb/c $\times$ CBA F1 mice. Antibody IgG was prepared from ascitic fluid by sequential precipitation with 2 mol/L of $(NH_4)_2SO_4$ and chromatography on Trisacryl-M-diethylaminoethanol (DEAE) (LKB-Produkter, Bromma, Sweden). The DEAE column was equilibrated in 5 mmol/L of sodium phosphate, pH 8.0, and the IgG was eluted using a linear gradient of 5 to 50 mmol/L of sodium phosphate at constant pH. For all therapy and analytical procedures described in this article, two IgG1 antibodies were pooled: number B5G1 (5.5 g) and A4E2 (1.6 g). Both yielded good immunofluorescence with the patient's cells in the presence of normal human serum, and neither gave any reaction with normal blood lymphocytes or with neoplastic B lymphocytes from three other patients. By flow cytometry, with one antibody fluoresceinated and the other not, they

revealed strong cross-inhibition. "Anti-Id IgG1" henceforth refers to this pool of two antibodies.

F(ab')₂ was prepared from the pooled IgG1 preparation by digestion with papain under standard conditions¹⁹: IgG1 20 mg/mL, papain 0.2 mg/mL in 0.1 mol/L of acetate buffer of pH 4.2, incubated at 37 °C for 18 hours, followed by chromatography on Sephacryl S300 (Pharmacia, Uppsala, Sweden) equilibrated in 0.1 mol/L of Tris HCl, pH 8.0.

Preparation of FabIgG. The preparation of FabIgG has been described in detail.¹¹ F(ab')₂ from antibody is reduced with 2-mercaptoethanol under the minimal conditions, giving a high yield of monomeric Fab'γ. Next, the liberated SH groups are allowed to react with a surplus of *o*-phenylenedimaleimide to give Fab'γ bearing a small number of active maleimide groups attached predominantly to its hinge region. The Fab'γ then reacts with human normal IgG that has previously been reduced with a limiting amount of dithiothreitol to give an average of <3.0 SH groups per molecule. The two reactants are mixed in a molar ratio of Fab'γ:IgG = 1:2 and incubated at 5 °C for 24 hours. The FabIgG is then separated from larger products and from residual reactants by recycling chromatography through Sephacryl S300 (Pharmacia) equilibrated with PBS. Typically, ~600 mg of FabIgG is collected from the column system in ~1,100 mL. Some surplus normal IgG contaminates the tail of the FabIgG zone, but this is regarded as of no consequence for therapeutic purposes. The yield of Fab'γ in the chimeric antibody was usually ~40% of that used in the synthesis.

Infusion of antibodies. The procedure for infusion of antibodies was essentially the same for both IgG and FabIgG. Any aggregated protein was removed from the preparations by passage through Sephacryl S300 and was equilibrated with sterile, pyrogen-free, PBS. For FabIgG, this corresponded with the purification procedure described previously. From the S300, the final antibody-containing effluent was led through a polymyxin column²⁰ to remove any pyrogens, and then through a 0.22-μm filter (Millipore, Harrow, England) directly into a sterile IV giving set. Aliquots from the giving set were tested for pyrogens by the limulus amoebocyte method (Pyrogen test, Mallinckrodt, Round Spinney, Northants, England) and always proved negative.

Twenty-four hours before the infusion was started, allopurinol 300 mg daily was started. At this time also, a serum sample was examined by micro-Ouchterlony technique for precipitins to mouse Ig, the method being capable of detecting antibody at <10 μg/mL. One hour before the infusion, a cutaneous prick test was performed to test for immediate hypersensitivity to the antibody.

Infusions, consisting of 200 mg of anti-Id IgG1 or 380 to 580 mg of anti-Id FabIgG, were given in a volume of 600 to 1,200 mL over 6 hours. The infusions of FabIgG were accompanied by up to 300 mg of human normal IgG, representing incompletely separated surplus reactant. A close watch was kept on temperature, pulse, and respiration.

Microassays. Our general procedure for ELISA has been described.¹⁷ For measurement of either FabIgG or mouse IgG in the patient's serum, the plate was coated with affinity-purified rabbit anti-mouse IgG at 5 μg/mL; this antibody had previously been absorbed with human Ig. The standard antigen was FabIgG or mouse IgG, corresponding to the unknown, used at starting concentrations of 200 and 20 ng/mL, respectively. Detection of bound antigen used the same rabbit anti-mouse IgG, conjugated to horseradish peroxidase and used at a dilution of 1:500.

To assay the patient's serum for the presence of idiotype-positive IgM, the ELISA plate was coated with monoclonal anti-Id using a solution at 5 μg/mL; the standard antigen was the supernatant of the IgM-secreting rescue hybridoma, and the detecting antibody was affinity-purified goat anti-human μ chain conjugated to horseradish peroxidase (1:1000) used with normal mouse serum (1:500).

Assessment of antibody in vitro. Tests for antibody-mediated complement lysis and for antibody-dependent cellular cytotoxicity (ADCC) were carried out by standard methods as previously described.²¹ Distribution of surface antigen-antibody complexes was visualized by indirect immunofluorescence,¹³ with flow cytometry carried out on the Becton Dickinson FACS III system.

RESULTS

Studies on tumor cells in vitro. Markers found on nodal and blood lymphocytes are summarized in Table 1. The surface Ig (IgMλ, with IgDλ just detectable on a minority of cells) was at a low level on all cells, being about equal to the average density observed in cases of chronic lymphocytic leukemia (CLL). About half the cells showed detectable class II histocompatibility antigen, whereas all stained for CD5, a pan-T marker that also appears on most cases of CLL and on some B cell lymphomas; in our experience, these findings are exceptional for this type of lymphoma.

A sample of blood lymphocytes prepared in February 1984 appeared from marker studies to consist of at least 80% tumor cells. When the cells were cultured for 6.5 hours in vitro, they secreted Ig as follows²²: κ chain 1500 and λ chain 6,400 dimeric molecules per cell per hour and IgM 130 monomeric molecules per cell per hour. This represented minimal IgM secretion by the tumor, and led to the expectation, confirmed later, that only a small barrier of idiotype Ig existed in the patient's plasma.

As we observed earlier⁵ with tumor cells having sparse surface Ig, no anti-Ig antibody tried would invoke complement lysis, using either human AB or rabbit serum as a source of complement. The antibodies tried included the monoclonal anti-Id, the FabIgG prepared from it, sheep polyclonal anti-Fdμ, and sheep polyclonal anti-λ. Neither would any of these antibodies invoke ADCC in the presence of human normal blood lymphocytes at an effector to target ratio of 50.

Fig 2. Modulation of blood lymphocytes in vitro by IgG1 and FabIgG anti-idiotype antibody (anti-Id) shown by cytofluorimetry of indirect immunofluorescence. x-axis, fluorescence (linear scale set at half-maximum gain); y-axis, cell number. Indicator antibodies: for IgG1, fluoresceinated rabbit anti-mouse IgG; for FabIgG, fluoresceinated rabbit anti-human Fcγ. Control (0 °C): cells (1.5 × 10⁷/mL) and antibody (IgG1 100 μg/mL, FabIgG 250 μg/mL) were incubated at 0 °C for 30 min; indicator antibody was then added, and the suspension was maintained chilled during examination. Test (37 °C): cells and antibody were incubated at 37 °C for 30 min; they were then chilled, and indicator antibody was added. FabIgG at 37 °C induced only a minimal change in profile. Peaks nearest the y-axis are antigen negative.

Modulation, in the sense of clearing of antigen-antibody complexes from the tumor cell surfaces, occurred sluggishly in vitro in the presence of monoclonal anti-Id at 37 °C: after 30 minutes, possibly 50% of the integrated fluorescence seen on flow cytofluorimetry had disappeared. Modulation by FabIgG over the same period was slight or undetectable (Fig 2), whereas modulation by its Fab γ component alone was never observed.

Infusion of anti-Id IgG1. An infusion of 200 mg over 6 hours was tolerated without any symptoms. Changes seen in the blood lymphocyte count are shown in Table 2. The lowest count recorded occurred in midinfusion; from this point, the count rose steadily to its former level over 1 week. The tumor masses did not change. This is very similar to what we have seen previously with infusions of polyclonal anti-Id^{3,5} and to what has been recorded for therapy with a variety of monoclonal antibodies.¹

Infusions of FabIgG. The clinical effects of each of four infusions were very similar. No symptoms were noted during the infusions. Beginning 6 hours after completion and continuing for 24 hours, the patient suffered nasal congestion, edema of the eyelids, mild pyrexia (37.5 °C), and mild abdominal pain. Four days after completion of infusion, lymph nodes in all areas were swollen, reaching about twice their previous size, remaining enlarged for 5 to 8 days, and then subsiding. There were no corresponding changes in splenic size.

Lymphocyte counts at midinfusion showed falls similar to that observed with IgG1 antibody (Table 2). The postinfusion nadir did not occur immediately after the infusion, however, but ~1 day later. From this point, the count again rose slowly, with the troughs more prolonged than after the IgG1 infusion.

A rise in C3c concentration in serum was evidence of complement activation. Thus, 7 hours after the second FabIgG infusion was started, crossed immunoelectrophoresis gave a strong peak for C3c. This was maximal at 24 hours and subsiding at 48 and 72 hours.

Following the third FabIgG infusion, with the associated nodal swelling and subsidence, a marked net diminution in the size of palpable tumor was obvious. Physical examination showed that the cervical masses had shrunk to $\leq 50\%$ of their initial volume and that the splenic edge had retreated to the costal margin. In the 11 weeks following the fourth FabIgG infusion, the tumor masses either remained stationary or subsided further, whereas the blood lymphocyte count dimin-

Fig 3. Serial lymphocyte counts related to antibody infusions. Day 1 is the day of IgG1 infusion (January 15, 1985).

ished to $3.1 \times 10^9/L$, ~40% of the pretreatment level (Fig 3).

In the ensuing 4 months, the patient remained well, with tumor masses unchanged and hemoglobin and granulocyte levels well maintained. The lymphocyte count, remarkably, dropped even more, to $2.4 \times 10^9/L$. Of these cells, >80% were idiotype-positive and only 7% were scored as T cells. On the tumor cells, the surface Ig appeared to be at about its original density, and reaction with the monoclonal anti-Id was undiminished. At no time during or after antibody treatment could antibody to mouse Ig be detected in the patient's plasma.

Plasma idiotype and antibody levels. Throughout the period of treatment, the plasma idiotypic IgM was at 0.9 to 1.4 $\mu g/mL$, except during the immediate postinfusion periods when, with free antibody in the plasma, the concentration fell to <0.3 $\mu g/mL$. These levels are much lower than those we have found in most B cell neoplasms.⁸

After all antibody infusions, both IgG1 and FabIgG, the antibody (assayed as mouse Fab γ) disappeared from the plasma with a $t_{1/2}$ of <24 hours. In the later FabIgG infusions, this was regarded with disappointment, as calculations had suggested that the antibody should have been sufficient to swamp both the extracellular and the cell surface idiotypic IgM. We believed it was important to confirm that the FabIgG was being consumed rapidly because of its antibody activity and not because of some unexpected metabolic fate such as scavenging by macrophages. The patient therefore consented to a control infusion

Table 2. Lymphocyte Counts Following Antibody Infusions

Antibody Preparation	Day of Infusion	Counts ($10^9/L$) at Times Related to Starting Infusions						
		-1 h	3 h*	7 h	1 day	2 days	3 days	6-8 days
IgG1								
200 mg	1	7.8	2.5	3.9	4.1	6.0	5.8	7.9
FabIgG								
480 mg	15	6.4	2.5	5.7	2.8		3.7	6.8
380 mg	50	7.9	3.5	7.7	1.2	2.9	4.1	5.6
450 mg	64	7.0	1.4	5.4	2.9	3.8	4.3	5.7
580 mg	92	5.3	2.2	4.3	2.7	2.6	2.8	5.1

*At midpoint of infusion.

of FabIgG in which the Fab'γ moiety had anti-Id activity against guinea pig L₂C cells and no activity against either her tumor cells or normal human lymphocytes; the IgG moiety was again normal human. Two weeks after the fourth therapeutic lot of FabIgG, the patient received a 6-hour infusion of 150 mg of the control material. There were no symptoms and no significant changes in lymphocyte counts. Plasma levels of mouse Fab'γ estimated for 1 week after the infusion revealed a $t_{1/2}$ > 10 days (Fig 4), comparable with the value of ~20 days expected for human normal IgG.²³

Qualitative studies of tumor cells. Reports on blood films from the hematology laboratory always indicated an increase in "smear" cells among the lymphocyte populations in immediate postinfusion periods: for example, these cells usually represented 10% to 15% of lymphocytes before an infusion but were reported at 50% 24 hours after the IgG1 antibody and at 43% 24 hours after the first lot of FabIgG antibody.

Observations of bound antibody and of modulation of surface antigen-antibody complexes were rendered difficult by the sparseness of surface Ig. Immediately after the IgG1 infusion immunofluorescence detected a diminution in the surface Ig; this was attributed to modulation. More surprisingly, flow cytofluorimetry revealed similar decreases in surface Ig after infusions of FabIgG. In Fig 5, the distributions of surface Ig on blood lymphocytes are shown at times related to the first FabIgG infusion. At 7 hours, 1 hour after the end of the infusion, all three anti-Ig antibodies used revealed diminished reactivity. At 24 hours, the profiles were essentially unchanged. At 3 days, the reactivities were still not completely restored, especially with anti-Id. Very similar appearances occurred after the ensuing three FabIgG infusions.

The diminution in detectable surface Ig may have been due to blocking of indicator antibodies by therapeutic antibody, to modulation, or to preferential removal by therapeutic antibody of cells with higher than average densities of surface Ig. We believe that modulation is probably the major cause, although patching and internalization could not be judged confidently by fluorescence microscopy. Residual therapeutic antibody could not have had a significant blocking role, as none could be detected on the cells by fluorescein-

Fig 4. Rates of disappearance of antibody and control FabIgG from the patient's plasma. The antibody was the fourth infusion of anti-idiotype antibody (anti-Id) FabIgG. The first samples assayed were taken 1 hour after a 6-hour infusion.

Fig 5. Surface Ig on blood lymphocytes before and after the first infusion of anti-idiotype antibody (anti-Id) FabIgG, demonstrated by flow cytofluorimetry. Axes: horizontal, degree of fluorescence; vertical, cell number. Idiotypic, μ and λ determinants were examined separately and are shown in separate columns. Idiotype was revealed by indirect immunofluorescence with anti-Id IgG1 as first antibody and fluoresceinated rabbit anti-mouse IgG as second antibody; μ and λ chains were revealed by direct fluorescence using affinity-purified rabbit antibodies. Time 0 is the beginning of the 6-hour infusion. Antigen-negative cells form a left-hand peak in the patterns at -1 hour and 3 days, but merge with the Ig-bearing peak in the 7-hour patterns.

ated anti-human Fcγ. Finally, the diminution in lymphocyte count at 7 hours, even if highly selective, does not seem sufficient in itself to have yielded so pronounced a change in surface Ig profiles. At no stage related to any of the infusions was the complement component C3 detected on blood lymphocytes by immunofluorescence.

Needle aspirates of cervical tumor masses were taken 14 days after the first FabIgG infusion as the masses were subsiding, and 2 days after the third FabIgG infusion before any infusion-related changes in size occurred. In the first aspirate, cytospin preparations revealed 74% tumor cells (λ -bearing) and 23% T cells (CD3-bearing). In the second aspirate, these figures were 69% and 21%, respectively; the tumor cells were predominantly large and atypical, many with one to three nucleoli. In neither preparation could the infused antibody be detected on cell surfaces.

DISCUSSION

No conclusions about the therapeutic efficacy of FabIgG are drawn from this case except that the derivative is at least capable under certain conditions of reducing tumor load. Non-Hodgkin's lymphoma is notorious for waxing and waning without obvious cause or following an apparently irrelevant event such as intercurrent infection.^{24,25} In the present case, there is no obvious reason for the reduced amount of tumor having apparently stabilized after termination of the

infusions, with indeed an actual further reduction in the number of circulating neoplastic cells. Clearly, one must bear in mind the possibility that antibody treatment of lymphoma may not only be cytotoxic, but may also trigger poorly understood immunoregulatory pathways.²⁶

Because of overall disappointing results in antibody therapy in lymphoma,^{1,5-7} some modification of the approach appears indicated. Apart from the mere addition of antibody to existing drug schedules, two main lines of development are being considered. One is the use of antibody as a vector to deliver a more lethal agent (radioisotope, tumoricidal drug, plant or bacterial toxin) to the cell. The other, adopted here, attempts to make better use of the cytotoxic effector mechanism normally recruited by antibody. The best known of these mechanisms are complement, phagocytes, and K cells. Unfortunately, we have no clear indications of their relative importance in dealing with antibody-coated lymphoma cells.⁸ We can assert, however, that a major advantage of relying on any of these mechanisms is that they contain an inbuilt safety factor in addition to the specificity of antibody: to activate any of the effectors, antibody must form a sufficient array on the cell surface, oriented with its Fc zones outward. Weak cross-reactions of the antibody with normal cells or the uptake of antigen-antibody complexes by bystander cells are unlikely to be harmful.

Univalent derivatives of antibody which retain intact Fc zones are superior to their bivalent parent antibodies in invoking killing of mammalian cell targets by natural effector mechanisms.^{9-11,27} Their superiority derives from their avoidance of rapid antigenic modulation, which can afford significant protection to a cell confronted simultaneously by bivalent antibody and an effector such as complement.^{13,28} The chimeric univalent antibodies FabFc¹⁰ and FabIgG (Fig 1) are developments of the univalent concept, presenting additional advantages from the possession of a human Fc γ zone. Such derivatives clearly are potentially varied and—especially if one includes molecular genetic and hybridoma technologies—might be constructed in a large variety of ways.

With the target cells of this study, neither FabIgG nor the parent IgG1 antibody appeared to activate complement or ADCC *in vitro*. We suspect that the failure of FabIgG is due to the sparseness of surface antigen.⁵ Against different target cells, chimeric univalent antibodies, including FabIgG, have clearly demonstrated their abilities to activate both the effector systems.^{11,29,30}

Despite their lack of cytotoxic activity *in vitro*, both IgG1 and FabIgG antibodies reduced the numbers of circulating neoplastic cells after infusion. If each drop in lymphocyte count reflects cell death, the effector mechanisms must be more useful *in vivo* than is suggested by performance *in vitro*. But could the drop be due more to temporary sequestration than to death of the cells? Attempts to answer this have been made in earlier studies^{31,32} by infusing antibody after indium-labeling of the blood lymphocytes. The results suggested cell death as the main mechanism because labeled cells disappearing on antibody infusion did not subsequently reappear in the blood in quantity. In the present work, the simple observation of a marked increase in smear cells

suggests a range of damage compatible with extensive cell death.

We are not aware of any previous report of tumor becoming swollen and tender in response to antibody therapy in the manner shown by the nodal masses in our patient. Because it occurred only with FabIgG infusions, and because the FabIgG but not the IgG1 antibody activates complement, it is tempting to regard this inflammation as complement-induced. The delay in onset for several days after each infusion is then difficult to explain, however. Examination of nodal aspirates did not help: in particular, granulocytes evidently were not recruited by complement peptides. Unfortunately, our patient was unwilling to undergo an excision biopsy that might have revealed more useful information. Garcia and colleagues³³ recently described the lymphoid histology in ten patients treated with monoclonal anti-Id, with evidence that clinical remission is more likely the greater the number of infiltrating T cells and the greater the incidence of CD4 (helper), CD25 (TAC), and Leu-7 (NK) positivity among them.

The mild symptoms suffered by the patient ~6 hours after each FabIgG infusion were possibly due to complement anaphylatoxins and/or to interleukin-1 from stimulated macrophages.

The modulation of surface Ig which appeared to be induced by FabIgG *in vivo* exceeded anything inducible by the same derivative *in vitro*. Evidence shows for the mouse Ia system that antibodies that do not modulate *in vitro* can do so *in vivo*.³⁴ Monocytes in the capacity of bystander cells have clearly promoted or even induced modulation of antibody on target cells,³⁵ raising the possibility that enhanced modulation *in vivo* in the present case was due to interaction of the bound FabIgG with FC γ -receptors on various cells.

Although the modulation by bivalent and univalent antibodies *in vivo* appeared similar, the time course cannot be followed with the same precision as is possible *in vitro*. The speed with which bivalent anti-Ig can induce modulation *in vitro* is sufficient to provide significant protection to a cell exposed simultaneously to antibody and complement.¹³ Neither we nor others observed such rapid modulation by univalent antibody.^{12,13} It therefore remains entirely possible that the modulation induced by univalent antibody *in vivo* is slower, and hence less protective, than that induced by bivalent antibody.

At the time of the fourth FabIgG infusion, the total idiotypic IgM harbored by the patient was estimated crudely at <50 mg based on a plasma level of 1 μ g/mL, an extravascular fluid load equal to the intravascular fluid load, a tumor burden <2 $\times 10^{12}$ cells, 20,000 molecules of monomer per cell surface, and an intracellular pool of the same size. The rate at which the infused antibody disappeared, in contrast to nonantibody FabIgG (Fig 4) indicates that our calculation was a gross underestimate. (Another explanation for the much briefer survival of the antibody FabIgG is that the patient herself was mounting an anti-Id response against the antibody. No increase in blocking activity was present in her plasma to support this suggestion.) Possibly, the large spleen contained unsuspected quantities of idiotypic Ig, although findings by Meeker and

co-workers⁶ on two similar patients subjected to splenectomy do not support this notion. It can be expected that saturation of antigenic sites would leave surplus antibody FabIgG with $t_{1/2}$ comparable to that of the control. With such a metabolic survival, the FabIgG would represent quite an economic means of using antibody to provide a prolonged attack on the tumor.

No anti-mouse Ig response has been observed in this patient. In animals, FabIgG containing homologous IgG but xenogeneic Fab elicits a much lower antibody response than does the corresponding xenogeneic IgG.¹¹ Therefore, there are grounds for hoping that avoidance of xenogeneic Fc γ will reduce the problem of anti-Ig responses by the patient

following therapy with monoclonal antibody. The idiotypic and mouse Fd γ determinants on FabIgG remain potential immunological targets. We shall continue to observe this patient closely. Our present intention is to reinstitute antibody treatment when the neoplasm appears to be expanding again.

ACKNOWLEDGMENT

We are indebted to Alan Pindar for his care in preparing FabIgG, to Dr Frank Paul for flow cytometry, to Dr John Smith and his staff for many immunological investigations, and to Mary Caddy and Julia Nye for preparing the manuscript.

Plasminogen Activator Inhibitor: A Regulator of Ancrod-Induced Fibrin Deposition in Rabbits

By Chitra Krishnamurti, Charles F. Barr, M. Alycia Hassett, G. David Young, and Barbara M. Alving

Plasma levels of a fast-acting plasminogen activator inhibitor (PAI), which neutralizes both tissue plasminogen activator (t-PA) and urokinase, are markedly increased in endotoxin-treated rabbits. The ability of this inhibitor to prevent the fibrinolysis that occurs after a thrombogenic stimulus was investigated in a rabbit model. Normal and endotoxin-treated male New Zealand rabbits were infused with ancrod, an enzyme that causes noncrosslinked fibrin formation *in vivo*. Ancrod stimulated t-PA activity by 90% in normal rabbits and caused hypofibrinogenemia but did not increase PAI levels or induce fibrin deposition in target organs. Rabbits injected with endotoxin (10 µg/kg)

showed an increase in PAI from <1 to 32 U/mL 4 hours later. When ancrod was infused at this time, 90% of the rabbits developed renal fibrin thrombi. Fibrin deposition was recorded in 40% of the rabbits that received a lower dose of endotoxin (1.0 µg/kg) and had a PAI level of 14 U/mL at the time of ancrod infusion 4 hours later. Fibrin deposition did not occur in the endotoxin-treated rabbits that received normal saline. These data suggest that high levels of PAI inhibit fibrinolysis *in vivo*, thereby promoting fibrin clot deposition following a thrombogenic stimulus.

This is a US Government work. There are no restrictions on its use.

TWO CRITICAL FACTORS in the regulation of fibrinolysis *in vivo* are the functional levels of tissue-type plasminogen activator (t-PA) and plasminogen activator inhibitor (PAI), both of which are identical to those produced by endothelial cells.¹⁻³ PAI, a 50,000-mol-wt protein, has an apparent half-life ($t_{1/2}$) of 7 minutes when measured in the rabbit circulation⁴ and is the major inhibitor of t-PA and urokinase in both humans⁵ and rabbits.^{4,6} Elevated levels of PAI have been found in plasma from patients who have had venous thromboses,^{7,8} gram-negative sepsis,^{4,9} and many other conditions predisposing to fibrin clot formation.¹⁰

Colucci and co-workers⁴ demonstrated that infusion of endotoxin into rabbits increases PAI levels in a dose-dependent manner; they postulated that high levels of this inhibitor may have a physiologic role in the coagulopathy associated with endotoxemia. Although other investigators showed that infusion of soluble fibrin into endotoxin-treated rabbits results in renal microclot formation,¹¹ whether the apparent inhibition of fibrinolysis by endotoxin is mediated through its ability to increase levels of circulating PAI is not known.

The present study used endotoxin-treated rabbits to determine if elevated PAI levels could inhibit the fibrinolysis that occurs after infusion of ancrod, an enzyme that induces non-crosslinked fibrin clots by cleaving fibrinopeptides A, AP, and AY.¹²⁻¹⁴ Ancrod causes hypofibrinogenemia and elevated titers of fibrinogen-fibrin degradation products (FDP-fdp) when infused slowly into rabbits and humans.^{15,16}

This study demonstrates that ancrod does not cause fibrin deposition in normal rabbits, presumably because of the

fibrinolysis that occurs in response to its initial coagulant action. Ancrod can, however, induce fibrin deposition in animals that have elevated levels of PAI. The data indicate that PAI may promote fibrin formation by preventing the endogenous fibrinolysis that occurs after a thrombogenic stimulus.

MATERIALS AND METHODS

Materials. Purified two-chain human t-PA was purchased from American Diagnostica, Greenwich, CT. The specific activity was 100,000 U/mg, as determined with an international urokinase standard; the data in this article are expressed in terms of this standard. If this preparation of t-PA were calibrated against the International Reference Preparation for t-PA,¹⁷ the specific activity would be ~500,000 IU/mg.¹⁸ Urokinase (specific activity, 100,000 U/mg) was purchased from Abbott Laboratories, North Chicago. Human fibrinogen and Cohn fraction III paste were obtained from Cutter Laboratories, Berkeley, CA. Plasminogen was purified from the paste by affinity chromatography¹⁹ on lysine-Sepharose (Pharmacia Fine Chemicals, Uppsala, Sweden); the specific activity was 20 CTA U/mg. Human thrombin (H-2) and human plasmin (7.3 U/mg) were supplied by the Office of Biologics, Bethesda, MD. The synthetic substrate D-Val-Leu-Lys-pNA (S-2251) was purchased from Kabi Diagnostica, Stockholm. Ancrod, an enzyme derived from the Malayan pit viper, was the generous gift of Knoll Pharmaceutical, Whippany, NJ, and endotoxin (*Escherichia coli* 0111:B4) was purchased from Difco Laboratories, Detroit.

Animal experiments. Male New Zealand white rabbits weighing between 2.3 and 3.5 kg were received from a single supplier at least 1 week before use and were given standard laboratory food and water *ad libitum*. Endotoxin was infused into a marginal ear vein during 5 minutes in a total volume of 3 mL of normal saline at a dose of 1.0 or 10.0 µg/kg. Ancrod (2 U/kg) was administered by an infusion pump in a total volume of 20 mL of normal saline into a marginal ear vein during 1 hour. The vasopressin analogue 1-desamino-8-D-arginine vasopressin (DDAVP, Armour Pharmaceutical, Kankakee, IL) was infused into a marginal ear vein during 10 minutes at a dose of 0.4 µg/kg in 10 mL of normal saline. Blood samples (0.9 mL) were collected from the uninfused marginal ear vein into polypropylene tubes that contained 0.1 mL of 2% EDTA and immediately centrifuged for 1 minute at 22 °C in an Eppendorf centrifuge 3200 (Brinkman Instruments, Westbury, NY). The plasma was immediately separated from the RBCs, and aliquots were stored at -70 °C or acidified in preparation for measurement of plasminogen activator.

Assay of plasminogen activator activity. Assay for plasminogen activator activity was performed according to the method of Wiman

and colleagues.²⁰ Plasma was acidified with an equal volume of 1.0 mol/L of sodium acetate pH 3.9 and incubated at 22 °C for 15 minutes. An aliquot of this mixture was diluted to a final plasma concentration of 0.5% in 0.05 mol/L of Tris, 0.1 mol/L NaCl, and 0.1% Triton X-100 pH 8.8 (NEN, Boston), and incubated with 1 mmol/L of S-2251 and 0.3 mg/mL of plasminogen in the presence of fibrin (70 µg/mL) for 6 hours at 37 °C in a microtiter plate. The change in absorbance was measured at 405 nm with a Titertek Multiscan Spectrophotometer (Flow Lab, McLean, VA).

Assay of PAI activity. The PAI assay was performed as described by Chmielewska and colleagues.²¹ Human t-PA (10 µL, 2U/mL final) was incubated for 10 minutes at 22 °C with 40 µL of plasma that was undiluted or diluted in 0.02 mol/L of sodium phosphate, 0.1 mol/L of NaCl pH 7.3. Residual t-PA activity was measured after acidification and dilution of the sample as described previously. One unit of inhibitor is defined as the amount that inactivates 1 U of t-PA during the 10-minute incubation period.

Assay of plasmin-inhibitor activity. Plasmin (final concentration 0.6 CTA U/mL) was incubated for 20 seconds at 30 °C with rabbit plasmas diluted 1/20 and 3/40 in 0.05 mol/L of Tris and 0.15 mol/L of NaCl pH 7.4. After 20 seconds, a 30-µL sample was added to 1 mL of 0.1 mmol/L of S-2251 in 0.05 mol/L of Tris pH 7.4, and the change in absorbance at 405 nm was monitored with a Cary recording spectrophotometer (Varian Associates, Instrument Division, Palo Alto, CA). The results were expressed as the percentage of activity of a standard of pooled human plasma.

Plasma plasminogen assay. Plasma was mixed with an equal volume of 1.0 mol/L of sodium acetate pH 3.9 and diluted to final concentrations of 2% and 1% with 0.05 mol/L of Tris, 0.1 mol/L of lysine, and 0.1% human albumin, pH 7.4. A 200-µL mixture containing 0.05% to 2.5% plasma, urokinase (2,500 U), S-2251 (0.2 mmol/L) in Tris-lysine buffer was then incubated in a microtiter plate for 30 minutes at 22 °C, and the change in absorbance was compared with that obtained with a standard curve prepared from human plasmin of known activity.

Fibrin plate zymography. Plasma samples were electrophoresed in sodium dodecyl sulfate (SDS) on an 8% polyacrylamide gel that was then washed for 30 minutes in 0.1 mol/L of Tris pH 8 containing 0.1% Triton X-100.²² The gel was overlaid with a fibrin monolayer containing plasminogen, incubated at 37 °C for 16 hours, and photographed.²²

Fibrinogen and FDP-fdp. The fibrinogen concentration was determined spectrophotometrically after plasma was clotted with a calcium-thrombin solution for 1 hour, and the clot was washed with normal saline followed by solubilization in alkaline urea.¹⁵ The FDP-fdp were measured in a tanned RBC hemagglutination immunoassay that was modified for use in rabbits.¹⁵

Data analysis. The results of experiments were expressed as the mean ± SEM. Statistical analysis was performed with a Student's *t* test on paired samples.

Table 1. Measurement of PA Activity in Rabbit Plasma

Rabbit No.	PA (U/mL)		
	A	B	C
I	0.41	0.42	0.09
II	0.66	0.66	0.42
III	0.55	0.51	0.23
IV	0.74	0.60	0.34
Mean ± SEM	0.59 ± 0.07	0.55 ± 0.05	0.27 ± 0.07

Plasma was acidified, diluted to 0.5%, and assayed immediately (A); acidified, diluted, frozen at -70 °C for 24 hours and then thawed and assayed (B); acidified, frozen at -70 °C for 24 hours and then diluted and assayed (C).

Histopathology. Necropsies were performed on animals that died during anecrod infusion or were killed by a 5-mL intravenous (IV) injection of sodium pentobarbital (V-Pento C, 65 mg/mL) 1 hour after completion of the infusion. Within 20 minutes of death, tissues from all animals were immersion-fixed in neutral buffered 10% formalin, processed, embedded in paraffin, and stained with hematoxylin and eosin. Sections of lung, liver, kidney, and spleen were also stained with phosphotungstic acid hematoxylin (PTAH)²³ and examined for the presence of fibrin microthrombi by a pathologist who was unaware of the experimental protocol for the individual animals.

RESULTS

Measurement and characterization of PA in rabbit plasma. Although freezing acidified human plasma has been reported not to affect the PA activity,²⁰ freezing and storage of rabbit plasma at -70 °C caused a significant decrease in PA activity as compared with that of unfrozen samples (Table 1). When acidified rabbit plasma was diluted to a final plasma concentration of 0.5% in Triton X-100 buffer and then stored at -70 °C, the PA remained unchanged from that measured in fresh plasma. Therefore, all plasmas were stored at -70 °C after acidification and dilution in Triton X-100 buffer. The apparent lability of rabbit PA could not be explained on the basis of qualitative or quantitative alterations in activators or inhibitors. Both species have similar levels of PAI and PA⁶; by fibrin zymography, the mol wt of PA in rabbit plasma is 68,000, similar to that of human t-PA.⁶ The PAI in rabbit plasma has the same mol wt as the PAI that has been characterized in human plasma.⁴

Effects of anecrod infusion in normal rabbits. When anecrod was infused into normal rabbits, fibrinogen levels decreased from 2.2 ± 0.1 to 0.3 ± 0.1 g/L and FDP-fdp increased from a baseline titer of 1/32 to 1/4098 at 1.5 hours after initiation of the infusion. These alterations were associated with a significant increase in PA activity of 91.3% ± 16.1% (*P* < .01, Fig 1). Six hours later, the PA levels had returned to baseline values, and the fibrinogen levels were still depressed (0.4 g/L). When anecrod was infused at this time into these hypofibrinogenemic rabbits, PA activity was again increased by 40.7% ± 14.6% above the 6-hour value

Fig 1. Effect of anecrod on plasminogen activator (PA) activity in hypofibrinogenemic rabbits. Anecrod (2 U/kg) was infused at 0 and 6 hours. PA activity (—) and fibrinogen levels (---) were determined at the indicated time points. Data are the mean ± SEM of four rabbits.

Fig 2. Fibrin zymogram of paired rabbit plasmas obtained before and 1.5 hours after infusion of ancrod or saline. Samples were electrophoresed in sodium dodecyl sulfate (SDS) on an 8% polyacrylamide gel. Lanes 1,3, pre-ancrod samples, lanes 2,4, post-ancrod; lanes 5,7, pre-saline; lanes 6,8, post-saline; lane 9, human-melanoma tissue plasminogen activator (t-PA); lane 10, human urokinase.

($P < .05$) and fibrinogen levels became undetectable. The PA values remained elevated for another 2 hours after the second ancrod infusion. By fibrin plate zymography, the PA before and after ancrod was 68,000 mol wt (Fig 2), suggesting that the increase in PA after ancrod was t-PA. Ancrod had no effect on PAI levels, which were <1 U/mL when measured before and at 1.5 hours after infusion. Infusions of saline into six control rabbits caused no increase in PA, PAI, or change in fibrinogen levels (data not shown).

To determine if ancrod could stimulate release of PA in the absence of any detectable fibrinogen, a group of animals was rendered afibrinogenemic by infusing ancrod at 0 to 1 hour and again at 2 to 3 hours (Fig 3). At 6 hours, these afibrinogenemic rabbits received either a third infusion of ancrod or DDAVP, which is known to stimulate PA in normal rabbits by 40%.⁶ Ancrod caused no increase in PA when infused at this time; however, PA was significantly increased by 26% ($P < .05$) in the five rabbits that had received DDAVP. These data indicate that ancrod stimulates PA release only when infused into rabbits that have circulating fibrinogen, suggesting that clot formation induced by ancrod is the stimulus for PA release. The ability of the afibrinogenemic rabbits to release PA when infused with DDAVP indicates that the PA stores had not been completely depleted by two previous infusions of ancrod.

Ancrod-induced fibrin deposition in endotoxin-treated rabbits. Infusion of endotoxin into rabbits caused a dose-dependent increase in both PA and PAI (Fig 4A and B). One group of rabbits received endotoxin at a dose of $1 \mu\text{g/kg}$, followed by an infusion of normal saline or ancrod 4 hours later (Fig 4A). Approximately 90 minutes after endotoxin infusion, PA was maximally increased by $41.2\% \pm 10.5\%$ above baseline values ($P < .01$), returning to normal values by 4 hours. PAI levels increased from <1 U/mL to maximum values of 14.3 ± 2.3 U/mL at 4 hours. Infusion of ancrod at this time did not cause an increase in PA, although fibrinogen levels decreased from 1.7 ± 0.3 to 0.1 ± 0.1 g/L. At necropsy, 40% of the rabbits had evidence of renal thrombi (Table 2). One of these animals also had pulmonary thrombi. None of the endotoxin-treated animals that received saline instead of ancrod showed any evidence of fibrin deposition.

A second group of rabbits was infused with endotoxin at a dose of $10 \mu\text{g/kg}$, followed by ancrod or normal saline 4 hours later. After infusion of endotoxin, PA was maximal at

30 minutes and declined at 90 minutes as PAI levels rapidly increased (Fig 4B). By 4 hours, PAI had increased from <1 to 32 U/mL; plasminogen levels had decreased from 5.9 to 4.2 U/mL, and α_2 -antiplasmin was decreased by 36%. Thus, the most striking change in components of the fibrinolytic system 4 hours after this dose of endotoxin was the marked increase in PAI. Infusion of ancrod at this time caused glomerular fibrin deposition in 90% of the animals (Table 2). One of these animals also had pulmonary thrombi, and one demonstrated pulmonary and splenic thrombi in addition to the fibrin deposition in the glomeruli (Fig 5). The endotoxin-treated animals that received saline had no demonstrable fibrin deposition.

These data suggested that endotoxin, by increasing PAI levels, promoted fibrin deposition in the ancrod-treated rabbits. The following experiment was done to determine if ancrod induced clot deposition when infused into endotoxin-treated rabbits that had PAI levels <1 U/mL at the time of initiation of infusion. Ancrod was infused into rabbits 30 minutes after they had received endotoxin ($10 \mu\text{g/kg}$). PAI levels increased from <1 to ~ 16 U/mL during the ancrod infusion and were 24 U/mL 1 hour later, at the time of necropsy. Fibrin deposition was detected in 50% of these rabbits (Table 2).

All rabbits infused with ancrod alone or with endotoxin at a dose of $1.0 \mu\text{g/kg}$ followed by ancrod survived the infusion.

Fig 3. Fibrinolytic response in rabbits after multiple infusions of ancrod. Plasminogen activator (PA) activity (—) and fibrinogen levels (---) were measured at the indicated time intervals after ancrod infusions at 0, 2 and 6 hours. Results are the mean $\pm$ SEM of five rabbits.

Fig 4. Effect of ancrod on endotoxin-treated rabbits. Endotoxin was administered at doses of 1 $\mu\text{g/kg}$ (A, 12 rabbits) or 10 $\mu\text{g/kg}$ (B, 13 rabbits), and ancrod was infused 4 hours later. The plasminogen activator (PA) (—) and PA inhibitor (PAI) (---) activities (mean $\pm$ SEM) are shown.

Animals that received endotoxin at the higher dose of 10 $\mu\text{g/kg}$ followed by ancrod at 30 minutes or 4 hours had mortalities of 50% and 40%, respectively. The mortality was 14% for those animals that received only saline 4 hours after this dose of endotoxin. Mortality could not be correlated with the presence of fibrin deposition.

DISCUSSION

The present study demonstrates that when a thrombogenic stimulus such as ancrod is infused slowly into normal rabbits, PA levels increase as a result of the coagulant action of ancrod on fibrinogen. PAI levels are not increased and fibrin deposition does not occur after ancrod infusion alone. However, rabbits that have a high level of PAI at the initiation of ancrod administration or rabbits that are undergoing rapid increases in PAI during the infusion may develop fibrin

deposition, predominantly in the glomeruli. It is unlikely that alterations in other components of the fibrinolytic system are sufficient to be implicated in the thrombus formation that occurred in endotoxin-treated rabbits that received ancrod. Although plasminogen levels decreased after endotoxin infusion, α_2 -antiplasmin levels were lower as well.

The infusion of endotoxin also causes leukopenia, generation of cellular and humoral procoagulant activity, and activation of the complement system.²⁴ These alterations, however, do not appear to be significant factors in the induction of fibrin formation described in the present study. In their work with rabbits deficient in the sixth component of complement, Muller-Berghaus and Lohmann demonstrated that the complement system does not have a role in the induction of renal microclot formation in animals that receive a continuous infusion of endotoxin.²⁵ Muller-Berghaus and coworkers also reported that rabbits injected simultaneously with ancrod and endotoxin developed glomerular microclots that could not be prevented by heparin²⁶ or by first rendering the animals neutropenic with nitrogen mustard.²⁷ They concluded that the endotoxin-mediated generation of

*Plasminogen activator inhibitor (PAI) levels at time of second infusion (ancrod or saline). For rabbits that received ancrod 30 minutes after endotoxin, PAI levels had not yet reached a plateau and increased from 0.2 to 24.7 U/mL at time of necropsy.

†Time of second infusion (ancrod or saline). After the administration of endotoxin, ancrod or saline was infused into the animals. Survivors were killed 1 hour postinfusion. Lung, liver, spleen, and kidneys were fixed, stained with phosphotungstic acid hematoxylin (PTAH), and examined for the presence of fibrin microthrombi.

Fig 5. Histopathologic evidence of fibrin microthrombi (dark, fibrillar areas) in the glomeruli of a rabbit infused with endotoxin (10 $\mu\text{g/kg}$) and then ancrod 4 hours later. The animal was killed 1 hour after completion of ancrod infusion.

microclots in anecrod-infused rabbits did not involve neutrophils or the generation of procoagulant activity by endotoxin.

Additional indirect evidence for the role of PAI in inhibiting fibrinolysis is suggested by the studies of Szczepanski and Lucer,²⁸ who reported that the infusion of a single dose of endotoxin into rabbits caused an increase in the fibrinolytic activity of the plasma euglobulin fraction within the first hour, followed by a decrease in the plasminogen activator activity of kidney tissue at ~6 hours. Bergstein and Michael²⁹ found that fibrinolytic activity was present in the renal cortices of rabbits killed 30 minutes after a single dose of endotoxin but was undetectable in animals killed from 1 to 2 hours later. The activity reappeared at 24 hours, thus following a time course consistent with induction of PAI. The loss of fibrinolytic activity after infusion of endotoxin alone was not associated with fibrin deposition.

The vulnerability of the kidneys of the endotoxin-treated rabbits to fibrin deposition after anecrod may reflect the low level of PA activity relative to the levels of PAI within this particular organ. In the present study, only 3 of 14 rabbits that developed renal fibrin deposition had pulmonary thrombi as well. One explanation for these findings is that

pulmonary tissue can have an inhibitory effect on the function of PAI, as was recently demonstrated by Colucci and co-workers.¹⁸ These investigators showed that addition of rabbit lung slices to a whole blood clot markedly enhanced its lysis when it was incubated in the presence of PAI inhibitor-rich plasma *in vitro*.

The highest levels of PAI appear to be induced by endotoxin in humans^{4,9} as well as in rabbits. However, the levels of PAI required to prevent fibrinolysis are not known for specific clinical settings. The levels may depend on the type of thrombogenic stimulus that is acting in a given situation. For example, anecrod induces non-crosslinked fibrin formation which undergoes lysis relatively easily. The generation of small amounts of thrombin which causes activation of coagulation factor XIII with crosslinking of α_2 -antiplasmin to the clot³⁰ may be much more thrombogenic and require larger concentrations of activator for lysis.

Elevated PAI levels appear to be a significant factor for clot formation when a thrombogenic stimulus such as anecrod is administered. Monitoring levels of this inhibitor in patients, especially those in sepsis, may allow prevention of renal fibrin deposition, which is not uncommon in this clinical condition.³¹

Culture From Human Bone Marrow of Blast Progenitor Cells With an Extensive Proliferative Capacity

By Scott D. Rowley, Saul J. Sharkis, Catherine Hattenburg, and Lyle L. Sensenbrenner

The investigation of human hematopoiesis is limited by the lack of an *in vitro* assay for the most primitive hematopoietic stem cell. In this report, we describe the culture from normal human bone marrow of unique colonies of morphologically immature cells with scanty, agranular, cytoplasm and a primitive nucleus with nucleoli. These "blast" cells demonstrate a significant ability for the generation of secondary colonies of multiple lineages, including additional blast cell colonies. These colonies are

detected at various times during the culture period of up to 28 days. Neither the time of appearance in primary culture nor any feature of the morphological appearance of the blast cells is correlated with replating ability or the differentiation pathway followed. The progenitor cell giving rise to these colonies may represent the earliest pluripotent hematopoietic stem cell yet grown in culture.

© 1987 by Grune & Stratton, Inc.

THE CURRENT general model of hematopoiesis assumes that mature blood cells arise from pluripotent hematopoietic stem cells capable of both self-renewal and differentiation.¹ Increasing maturation of the progenitor cell results in the loss of its self-renewal capacity and, concomitantly, a restriction in differentiation to a particular cell lineage. The clonal growth *in vitro* of hematopoietic cells supports this theory and facilitates the investigation of hematopoietic function. The cells of colonies arising in cultures of committed hematopoietic progenitors lack the primary features of stem cells, however, ie, an extensive ability for self-renewal and the ability to give rise to progeny of multiple lineages when replated. The most primitive progenitor cell described in cultures of human bone marrow so far, the CFU-GEMM,^{2,3} demonstrates only a limited capacity for self-renewal.⁴⁻⁶

Recently, murine progenitor cells capable of extensive replating and self-renewal were reported by several investigators.⁷⁻⁹ The cells of these colonies are morphologically immature ("blast cells") and, when replated, may give rise to secondary colonies of various lineages including additional blast cell colonies. This particular progenitor cell in one assay system demonstrates a "variable G₀ phase," with colonies appearing apparently randomly throughout the culture period.¹⁰ The work of Nakahata and colleagues with this primitive murine progenitor cell supports a stochastic model for hematopoietic stem cell differentiation.¹¹ Cultures of human umbilical cord blood give rise to similar colonies,^{6,12} although secondary colony formation when the blast cells are replated⁶ is much poorer than that reported for the murine cultures.^{7,11} To date, a similar cell has not been reported in cultures of

normal human bone marrow. In this report, we describe the growth from human bone marrow of primitive pluripotent cells that also have an extensive capability for the generation of secondary colonies. These cells may represent the earliest human hematopoietic stem cell grown *in vitro*.

MATERIALS AND METHODS

Bone marrow cells were aspirated from the posterior iliac crests of healthy human donors after informed consent was obtained. The collection of normal human bone marrow specimens is approved by the Joint Committee on Clinical Investigation of The Johns Hopkins University School of Medicine and The Johns Hopkins Hospital.

Cell culture. The assay for human blast cell colonies is modified from the technique previously described by Nakahata and Ogawa.⁶ Specifically, light density (sp gr < 1.077) mononuclear bone marrow cells obtained from Ficoll-Hypaque density-gradient centrifugation were cultured in α -MEM (GIBCO, Grand Island, NY), supplemented with 1.32% methylcellulose (1500 CP, Fisher), 30% fetal bovine serum (FBS, Hyclone, Logan, UT), 5×10^{-4} mol/L 2-mercaptoethanol, 5% conditioned medium (phytohemagglutinin-leukocyte-conditioned medium, PHA-LCM or tumor cell CM; described later), 1% bovine serum albumin (Sigma, St Louis), 10^{-6} mol/L of methylprednisolone sodium succinate ester, and 1 U/mL of recombinant human erythropoietin (Amgen, Thousand Oaks, CA). Quadruplicate 1-mL cultures of 50,000 bone marrow cells per culture dish (Lux, Miles Laboratories, Naperville, IL) were maintained in a 5% CO₂ humidified atmosphere at 37 °C for up to 29 days. Colonies derived from BFU-E, CFU-GM, and CFU-GEMM progenitor cells were scored on an inverted microscope after 14 to 16 days of culture. The dishes were returned to the incubator, and blast cell colonies (>20 cells) were scored after 26 to 29 days of culture (or as otherwise noted). All blast cell colonies were plucked from the culture dishes with a 10- μ L Eppendorf micropipette and resuspended in 100 μ L of α -MEM supplemented with 10% FBS. For replating experiments, one-half of the colony was immediately replated. The remaining cells were centrifuged onto glass slides for cytochemical staining (Wright's, specific and nonspecific esterases) and morphological examination.

Replating experiments. All colonies for replating were plucked from the primary culture as described previously after an estimation of colony size was made by *in situ* cell enumeration. One-half of the colony was immediately replated in the same conditions used for the primary cultures. Secondary colonies were scored after 14 to 16 days of culture and again after 26 to 29 days of culture. Clusters and colonies that appeared for only a few days early after replating (transient colonies) were not considered.

Conditioned medium. PHA-LCM was obtained from light-density (sp gr < 1.077) peripheral blood leukocytes from healthy human donors. The cells were suspended at 10^6 cells/mL in α -MEM supplemented with 20% FBS and 1% vol/vol of PHA (Wellcome

Laboratories, Beckenham, England). The flasks were maintained at 37 °C and 5% CO₂ for seven days. Cells and cellular debris were removed by centrifugation (400 g), and the supernatants were filtered (0.22 µm) and frozen in aliquots for use.

The CM¹³ obtained from culture of a hairy cell leukemia cell line (Mo-CM) was a gift of Dr David Golde (University of California at Los Angeles) and contained 5% FBS. The 5637-CM was derived from culture of a bladder tumor cell line.¹⁴

Nomenclature. We adopted the term blast cell for the cell giving rise to blast cell colonies in this assay.

Statistical analysis. Statistical analysis of the differences between numbers of colonies observed in cultures was performed using Student's two-tailed *t* test.

RESULTS

The blast cell colonies were loose homogeneous clusters of moderate-sized, translucent, round, agranular, and nonpigmented cells without evidence of myeloid or erythroid differentiation (Fig 1A); they appeared throughout the culture period (described later). This contrasted with the obvious red pigmentation of erythroid cells and the clearly mature cells with irregular outline, granular cytoplasm, and mature nucleus of BFU-E-derived and CFU-GM-derived colonies, respectively. Especially after 21 to 28 days of culture, the immature blast cell-containing colonies were easily distinguished from the more mature progenitor cell colonies, which

almost uniformly showed extensive degeneration. Also unlike colonies derived from the more mature progenitor cells, which on morphological examination frequently reveal cells comprising a wide range of maturation, the blast cell colonies consisted solely of blast cells with uniform morphological appearance (Fig 1B) except as noted below. Mitotic figures were commonly observed in cytospin preparations of blast cell colonies. The blast cells did not demonstrate either specific or nonspecific esterase staining. The blast cell colonies usually contained 200 to 500 cells, although colonies as small as 20 cells and as large as ~1,000 cells without maturation were observed. Frequently, the larger colonies contained a mixture of blast cells and foci of maturing cells. (These colonies were excluded from analysis since replates of these colonies invariably gave rise to very limited numbers of secondary colonies; CFU-GEMM replating efficiency is described below.)

The tumor cell CM supported increased blast cell colony growth as compared with the PHA-LCM (Table 1). This increase was approximately twofold to threefold and is statistically different ($P < .05$). Only a limited number of blast cell colonies were observed after 28 days of culture. We observed a mean ($\pm$ SEM, $n = 3$) of 3.7 ± 0.5 blast colonies in each milliliter of culture on day 14 of culture as compared with 0.9 ± 0.3 and 0.7 ± 0.2 on days 21 and 28 in a series of

experiments in which different sets of four plates were scored at each time point (difference in growth of blast cell colonies at day 14 and day 21 or day 28 was significant, $P < .05$). We did not score for blast cell colonies earlier than 14 days of culture to avoid confusion with the immature colonies of other lineages. Occasionally, small numbers of fully differentiated colonies without the usual extensive degeneration were observed after 28 days of culture. We presume that these colonies differentiated from blast cells present earlier in the culture period. Most (50% to 100%, mean 79%) of the blast cell colonies in this series contained progenitor cells that formed secondary colonies, and the replating efficiency was similar for the three time points. Blast cell colonies that did not replate (excluding colonies containing mature cells as described above) could not be distinguished on the basis of colony size or cytochemical staining of the individual cells from colonies with self-renewal capacity.

Blast cells dispersed into secondary cultures generated moderate numbers of secondary colonies of various lineages (Table 2), with some secondary blast cell colonies of 70 to 130 cells observed after an additional 28 days of culture. These secondary blast cell colonies have given rise to tertiary colonies (erythroid, granulocytic, not shown), but no tertiary blast cell colonies have yet been found. Mature granulocytic colonies replated after 14 or 28 days of primary culture and mature erythroid colonies replated after 14 days of culture did not give rise to secondary cultures. CFU-GEMM-derived colonies ($n = 10$) replated after 14 days of primary culture demonstrated some limited proliferative capacity. Three of these ten colonies, which contained an average of $2.8 \pm 0.5 \times 10^4$ cells, gave rise to 16, 7, and 16 granulocytic colonies, respectively. These replates had no secondary BFU-E, CFU-GEMM, or blast cell colonies.

The maturation pattern (Table 2) of colonies in the secondary cultures could not be predicted by the primary colony size or by cytochemical staining characteristics of cytospin preparations of the blast cells. We observed individual primary colonies giving rise to secondary colonies of erythroid or granulocytic lineages only, mixtures thereof, or some pluripotent progenitor cell colonies (CFU-GEMM or blast cell). Usually after 14 days of culture we did observe some primary colonies composed of cells similar to blast cells except appearing more opaque in situ. These cells contained early cytoplasmic granule formation with Wright's staining

and invariably gave rise to granulocytic colonies in secondary plating. Of 10 of these colonies from 5 bone marrow samples, 5 (50%) replated with a mean replating efficiency (number of secondary colonies grown per number of cells seeded) of 16.7%. These "late blast" colonies may have been derived from the more immature blast cell colonies, and may represent colonies that have become lineage restricted.

DISCUSSION

This report documents the presence in human bone marrow of hematopoietic progenitor cells that have a significant replating capacity suggestive of high proliferative potential and can be cultured in vitro. The colonies observed differ from those produced by the more mature progenitor cells by their variable time of appearance in culture (also seen in murine cultures of "S cells"¹⁰), in the uniform morphological appearance of the cells within and between blast cell colonies and, most importantly, in the ability to generate secondary colonies of multiple lineages, including additional pluripotent stem cell-derived colonies upon replating. We believe that these cells are functionally similar to those isolated from human umbilical cord blood^{6,13} and murine bone marrow and spleen.⁷⁻⁵ These cells may also be comparable to the human bone marrow progenitor cells giving rise to immature colonies in 5-day cultures on previously established adherent cell layers,¹⁵ although the differences in culture conditions make comparison difficult.

The tumor cell CM (Mo-CM or 5637-CM) resulted in increased growth of the blast cell colonies as compared with cultures of bone marrow with PHA-LCM. We did not determine if this increased growth relates to increased concentrations of particular growth factors contained within these media or the presence of an inhibitor(s) contained within the PHA-LCM. Additional evaluation of growth factor requirements for blast cell colony growth is under study. The observation by Keller and colleagues⁸ that initial co-culture of murine bone marrow cells with lymphocytes increased not only primary blast cell growth but also the secondary replating efficiency of the blast cells suggests that a specific growth factor (ie, lymphokine) may be important for optimal growth of the primitive stem cells. We did observe the growth of blast cell colonies from T cell-depleted cord blood,¹² which suggests the lymphocyte presence may not be required in this system, although lymphocytes may enhance the growth of blast cell colonies as shown for other progenitor cells.^{16,17}

We observed a marked heterogeneity of both the replating efficiency and lineage commitment in the secondary replates that could not be predicted by primary colony size or any other determined feature of morphological appearance. Mostly, we observed secondary replates containing only mature progenitor cell colonies (BFU-E, CFU-GM), although occasional CFU-GEMM and blast cell colonies were found. This definite tendency toward differentiation of the blast cells was also noted in human cord blood blast cell replates⁶; murine blast cells in one report retained significant self-renewal capacity,⁷ although blast cells from a different assay system have not been reported to generate any second-

*Blast cell colonies represent samples from 18 different bone marrow donors. This list is intended to demonstrate the range of proliferative potentials of the blast cells in replating experiments and does not show all replates from the 18 donors.

†Culture day is the number of days of primary culture at which time the blast cell colony is plucked for replating.

ary blast cell colonies.⁸ A particular set of culture conditions may select for differentiation over self-renewal. Even though the cells appear morphologically uniform, this is clearly not a reflection of their ability to reclone in secondary cultures (Table 2). Morphological appearance may not reflect the initial stages of differentiation and commitment, and other methods may be necessary to investigate the early stages of differentiation. Unlike leukemic blasts, the blast cells derived from normal tissues are not arrested in maturation, and differentiation should be expected of these cells if they are not merely an artifact of in vitro culture. In this regard, the late blasts observed in our culture system (type I blast of Keller and colleagues⁸) do demonstrate morphological evi-

dence of differentiation and a commitment to granulocytic maturation. The growth of more colonies than blast cells seeded in the replating experiments (Table 2) can be interpreted as a technical error in enumeration of the number of cells contained within the primary colony. Because we observed this on several occasions, we favor the hypothesis that the increase reflects the expansion of the blast cell pool and is consistent with the appearance of secondary blast cell colonies in the replates.

The blast colony progenitor cell appears to be more primitive than the CFU-GEMM in both human and murine hematopoiesis. The blast progenitor cell colony contains only immature cells, gives rise to both additional blast cell colo-

nies as well as mixed granulo-erythroid-megakaryocyte (CFU-GEMM) colonies when replated, and appears at various times after the establishment of culture, suggesting that the cell is in a resting state of cell cycle with a random entry into clonal growth. Only limited numbers of secondary colonies were found in replates of the CFU-GEMM colonies, and no secondary colonies were found in our replates of mature granulocytic or erythroid colonies. Blast cell colonies have not yet been demonstrated to arise from mixed colonies.

The blast cell appears to be functionally different from the more mature progenitor cells. We observed blast cell colonies grown from human bone marrows that have been exposed to 4-hydroperoxycyclophosphamide (4-HC)¹⁸ to "purge" tumor cells prior to autologous bone marrow transplantation.¹⁹ We and others also observed this relative resistance of the blast cell to 4-HC as compared with later progenitors in normal human bone marrow (data not shown) and in murine

spleen²⁰ samples, demonstrating a possible clinical benefit. Because these "purged" bone marrows are capable of reconstituting the hematopoietic system of the transplanted recipients, this blast cell may be the cell responsible for the reconstitution of hematopoiesis following bone marrow transplantation. The functional role of the blast progenitor cell in comparison to the mature progenitor cells is under active investigation at this center.²¹

This cell may represent the human hematopoietic stem cell, and this assay may serve as a fairly simple in vitro means to probe stem cell function. Certainly, this cell will merit further investigation including but not limited to its response to growth regulation and its role in the disordered states of hematopoiesis in humans.

Normal Synthesis and Expression of Endothelial IIb/IIIa in Glanzmann's Thrombasthenia

By J.C. Giltay, O.C. Leeksa, C. Breederveld, and J.A. van Mourik

Glanzmann's thrombasthenia is a bleeding disorder, inherited in an autosomal recessive way and characterized by an absence or deficiency of the platelet glycoprotein (GP) IIb/IIIa complex. Recently, we and others demonstrated that cultured human umbilical vein endothelial cells synthesize a membrane protein complex similar to the platelet GP IIb/IIIa complex. In this article, we demonstrate that endo-

thelial cells isolated from the umbilical vein of a newborn with Glanzmann's thrombasthenia, as compared with normal endothelial cells, show no difference in their ability to synthesize and express this GP IIb/IIIa complex. Our results indicate that Glanzmann's thrombasthenia is not accompanied by an "endotheliopathy."

© 1987 by Grune & Stratton, Inc.

DURING THE LAST few years endothelial cell properties, such as binding of fibrinogen,^{1,2} thrombin,³⁻⁶ and factors V,^{7,8} IX,⁹⁻¹¹ and X¹¹ have been described, suggesting an important role of the endothelial cell plasma membrane, analogous to the platelet membrane, in hemostasis and thrombosis.

In view of this endothelial cell receptor function, parallels were proposed between the endothelial and platelet plasma membrane. We and others demonstrated the synthesis by endothelial cells of a membrane glycoprotein (GP) indistinguishable from platelet GP IIa^{12,13} and of a protein complex similar to the platelet GP IIb/IIIa complex.¹³⁻¹⁵ Recently, endothelial cells were proposed to synthesize a protein immunologically related to platelet GP Ib as well.¹⁶

In Glanzmann's thrombasthenia, an autosomal recessive inherited hemorrhagic disease,^{17,18} the GP IIb/IIIa complex is absent or deficient on the platelet membrane. We wondered, therefore, whether thrombasthenic patients would have a deficiency, not only of the platelet GP IIb/IIIa complex, but also of the endothelial GP IIb/IIIa complex.

To attempt to answer this intriguing question we cultured endothelial cells isolated from the umbilical vein of a newborn with Glanzmann's thrombasthenia. We demonstrated, by immunofluorescence, crossed immunoelectrophoresis (CIE), and immunoprecipitation, that the patient's endothelial cells were indistinguishable from normal endothelial cells in their ability to synthesize and express a GP IIb/IIIa complex.

MATERIALS AND METHODS

Patient. The patient (Y.O., a boy) was born with petechiae and hematomas, despite a normal platelet count ($245 \times 10^9/L$). His parents, who were first cousins, were of Moroccan origin and had two older thrombasthenic children. The diagnosis of Glanzmann's thrombasthenia was based on the following criteria. The patient's platelets failed to aggregate in response to ADP or collagen but did aggregate in response to ristocetin. No binding of CLB-C17 (Table 1) or other anti-GP IIb/IIIa monoclonal antibodies was observed by indirect immunofluorescence or in a whole-blood binding assay.²⁰ No GP IIb/IIIa could be demonstrated by CIE (not shown) and two-dimensional nonreduced/reduced sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) (Fig 1).^{12,21}

Endothelial cell culture. Endothelial cells of the patient and those of normal controls were isolated from umbilical cords and cultured as described previously.¹²

Immunofluorescence. Endothelial cells were detached from culture flasks by brief exposure to 0.05% trypsin and 0.02% EDTA (wt/vol) (GIBCO, Paisley, Scotland), followed by neutralization with 300 $\mu g/mL$ of soybean-trypsin inhibitor (Sigma Chemical, St Louis). Cells were centrifuged, washed three times, and fixed with

1% paraformaldehyde as previously described for platelets.²² Binding of monoclonal antibodies and fluoresceine isothiocyanate (FITC)-labeled goat anti-mouse antibodies to either endothelial cells or platelets in suspension was quantitated with a fluorescence-activated cell sorter (EPICS Coulter, Hialeah, FL).

Crossed immunoelectrophoresis. Samples equivalent to 6×10^7 platelets or 1×10^6 endothelial cells were run against 3% and 1.2% (vol/vol) polyclonal rabbit antiplatelet antiserum, respectively, and an intermediate gel containing ¹²⁵I-labeled CLB-C17 IgG.^{12,14,20} Slides were stained with Coomassie brilliant blue and subsequently subjected to autoradiography.

Immunoprecipitation. Immunoprecipitation was performed as reported,¹² using a preformed complex of monoclonal antibodies and goat anti-mouse antibodies. Labeling procedures with ³⁵S-methionine and ¹²⁵I were as described,¹² with the exception that metabolic labeling with ³⁵S-methionine was not performed with endothelial cells on microcarriers but in 75-cm² culture flasks.

RESULTS

Immunofluorescence. CLB-C17, a monoclonal antibody directed against an epitope on the platelet and endothelial GP IIb/IIIa complex,^{12,19} bound to the same extent to the patient's endothelial cells as to control cells (Table 1), whereas no binding to the patient's platelets was observed. Values obtained with Glanzmann's thrombasthenia and concurrent control endothelial cells using CLB-C17 and CLB-HEC-75 (an anti-GP IIa antibody¹² that served as a positive control) were well within the normal range (63.4 ± 12.0 , 86.0 ± 4.3 , respectively, mean $\pm$ SD, $n = 5$).

Crossed immunoelectrophoresis. By CIE of an endothelial cell lysate against a polyclonal antiplatelet antiserum and ¹²⁵I-labeled CLB-C17, one precipitation arc could be visual-

Table 1. Binding of Monoclonal Antibodies to Endothelial Cells and Platelets in Suspension as Determined by Indirect Immunofluorescence

Subject	Platelets			Endothelial Cells		
	CLB-C17	CLB-HEC-75	NMS	CLB-C17	CLB-HEC-75	NMS
Glanzmann's thrombasthenia (patient Y.O.)	0.9	96.3	3.1	45.1	81.8	7.6
Control	92.1	93.6	1.7	57.3	89.2	18.0

NMS, normal mouse serum.

The numbers are percentages of platelets or endothelial cells showing a positive reaction (ie, above background). CLB-C17 recognizes an epitope on the glycoprotein (GP) IIb/IIIa complex.^{14,19} CLB-HEC-75 is an anti-GP IIa antibody¹² used as a positive control.

Fig 1. Analysis of platelet membrane glycoproteins (GPs) by nonreduced/reduced two-dimensional sodium dodecyl sulfate polyacrylamide gel electrophoresis. Autoradiogram of normal platelets (A) and the platelets of patient Y.O. (B). GP IIb and GP IIIa are absent in (B), whereas the other major GPs are present.

Fig 2. Crossed immunoelectrophoresis of Triton X-100 lysates of endothelial cells and platelets against a polyclonal antiplatelet antiserum. (A) Autoradiogram of normal endothelial cells; (B) autoradiogram of thrombasthenic endothelial cells; (C) autoradiogram of a mixture of normal and thrombasthenic endothelial cells, and (D) autoradiogram of normal platelets.

ized after autoradiography, using either a lysate of thrombasthenic cells (Fig 2B) or control cells (Fig 2A). To prove that both precipitation arcs had the same mobility, CIE of a mixture of both cell lysates was performed and again revealed one precipitation arc (Fig 2C).

Immunoprecipitation. CLB-C17 precipitated two proteins from lysates of metabolically (³⁵S methionine) as well as surface (¹²⁵I)-labeled thrombasthenic endothelial cells (Fig 3A, lanes 3 and 7). These proteins had the same mobility and were of an intensity equal to those precipitated from lysates of control cells (Fig 3A, lanes 2 and 6).

Antibodies against the platelet alloantigen Zw^a (PI^{A1}; located on GP IIIa,^{23,24} deficient on thrombasthenic platelets,^{25,26} and recently shown to be present on endothelial cells^{27,28}) gave precipitation results similar to those of CLB-C17 (not shown), indicating normal expression of the Zw^a (PI^{A1}) antigen by these thrombasthenic endothelial cells.

DISCUSSION

The endothelial cells isolated from the umbilical vein of our patient with Glanzmann's thrombasthenia, synthesize and express a protein complex that is qualitatively and quantitatively indistinguishable from the GP IIb/IIIa complex synthesized and expressed by normal endothelial cells. These findings indicate that Glanzmann's thrombasthenia is not accompanied by an "endotheliopathy," and are in keeping with the view of Nurden and colleagues²⁹ that the

Fig 3. Immunoprecipitation of endothelial cells either metabolically labeled with ^{35}S -methionine or surface-labeled with ^{125}I . (A) Nonreduced: lane 1, as a reference, ^{125}I -labeled IIb and IIIa precipitated with CLB-C17 from normal platelets (PL); lane 2, ^{35}S -labeled proteins precipitated with CLB-C17 from normal endothelial cells (N); lane 3, as in lane 2, using thrombasthenic endothelial cells (G); lane 4, ^{35}S -labeled IIa isolated with CLB-HEC-75 from normal endothelial cells; lane 5, as in lane 4, using thrombasthenic endothelial cells; lane 6, ^{125}I -labeled proteins precipitated with CLB-C17 from normal endothelial cells; lane 7, as in lane 6, using thrombasthenic endothelial cells; lane 8, ^{125}I -labeled IIa isolated with monoclonal antibody CLB-HEC-75 from normal endothelial cells; lane 9, as in lane 8, using thrombasthenic endothelial cells. (B) Reduced: lane 1 corresponds with lane 1 in A; lane 2 corresponds with lane 6 in A; and lane 3 corresponds with lane 7 in A.

structural genes coding for GP IIb and IIIa in this disease have no major defect. The platelet defect may be caused by a defect in a regulatory element affecting the transcription of both genes in megakaryocytes, as suggested by Bray and co-workers.³⁰

Platelet and endothelial GP IIb/IIIa are not identical, however. As shown previously^{13,14} and in this study, the electrophoretic mobility of the complexes and their subunits is different, as judged by CIE (Fig 2) and SDS-PAGE (Fig 3). Furthermore, not all of the monoclonal antibodies directed against platelet GP IIb/IIIa crossreact with endothelial GP IIb/IIIa,^{14,31} and, finally, in contrast to platelet GP IIb/IIIa, the endothelial complex cannot be dissociated by treatment with EDTA.^{13,14} Thus, although the endothelial GP IIb/IIIa complex is recognized by a number of anti-

platelet IIb/IIIa antibodies (including antibodies directed against the platelet alloantigen Zw^a (Pl^{A1})),^{27,28} structural differences are apparent.

Taking these findings together, we propose that the endothelial GP IIb/IIIa-like complex is encoded by genes that are similar but not identical to the genes coding for platelet GP IIb/IIIa. In this context, platelet GP IIb/IIIa seems to be structurally related to cell surface GPs of other cells, including lymphocytes and monocytes, and with these constitutes a family of molecules.³²⁻³⁴ The endothelial GP IIb/IIIa complex may belong to this family. More definite answers to these questions will be obtained by cloning the GP IIb/IIIa gene, allowing study at the DNA level to establish the structural features of the genes coding for the endothelial and platelet GP IIb/IIIa.

Human Neutrophil Elastase Alters Human α -Thrombin Function: Limited Proteolysis Near the γ -Cleavage Site Results in Decreased Fibrinogen Clotting and Platelet-Stimulatory Activity

By Mark S. Brower, Daniel A. Walz, Kimberly E. Garry, and John W. Fenton II

During blood coagulation, polymorphonuclear leukocytes release elastase in amounts that can exceed 100 nmol/L. We therefore studied the interaction between human leukocyte elastase and human α -thrombin. Elastase cleaved the thrombin B chain (Ala 150-Asn 151) near the γ -cleavage site, resulting in two fragments held together by noncovalent interactions. The NH_2 -terminal fragment (FI), mol wt ~18,000, was disulfide-linked to the thrombin A chain. The COOH-terminal fragment (FII), mol wt ~13,000, contained the active-site serine and formed a covalent bond with antithrombin III. Heparin accelerated proteolysis of α -thrombin by elastase. Proteolyzed α -

thrombin (T_α) retained full amidolytic activity; however, the concentration of T_α causing 50% maximal platelet aggregation and adenosine triphosphate (ATP) release was 7.9 nmol/L (1.1 nmol/L for α -thrombin and 220 nmol/L for γ -thrombin). Fibrinogen clotting activity of T_α and γ -thrombin was 32% and 1% that of α -thrombin, respectively. Elastase released during the coagulation process may modulate thrombin activity. In addition, elastase-modified thrombin may be a useful probe of the structure and function of the γ -cleavage region.

ELASTASE IS the major neutral protease released by human polymorphonuclear leukocytes (PMNs)¹ during blood coagulation or activation by soluble immune complexes, C5a, or endotoxin.¹⁻³ Elastase is released into the circulation in acute leukemia, in septicemia,⁴ and in a variety of other inflammatory conditions.³ Several studies suggest that the decrease in the concentration of coagulation factors that occurs in these conditions may be the result of direct proteolysis by PMN elastase.^{5,6} Elastase also inactivates human antithrombin III,⁷ α_2 -plasmin inhibitor, and C1 inactivator.⁸ Furthermore, it inhibits thrombin-induced platelet stimulation in association with limited proteolysis of platelet membrane glycoprotein Ib.⁹ In circulating blood, leukocyte elastase is inactivated mainly by α_1 -antitrypsin¹⁰; however, this inhibitor is readily inactivated by oxidizing agents such as those generated by phagocytosing PMNs.^{11,12} More recently, studies using cell contact systems have shown that α_1 -antitrypsin does not completely inhibit the proteolytic activity of PMN-derived elastase.^{13,14}

In this study, we investigated the effects of PMN elastase on human α -thrombin. PMN elastase cleaved the thrombin B chain at Ala 150-Asn 151, within four amino acids of the γ -cleavage site. Cleavage resulted in formation of a larger NH_2 -terminal and a smaller COOH-terminal fragment held together by noncovalent association. The elastase-modified thrombin possessed amidolytic activity similar to that of α -thrombin but exhibited reduced fibrinogen clotting and platelet-stimulatory activity. Elastase degradation of α -thrombin was enhanced by heparin. These findings suggest that elastase may be involved in the physiologic modulation of α -thrombin function.

MATERIALS AND METHODS

Human polymorphonuclear leukocyte elastase, specific activity 92%, was purified from outdated WBC concentrates or from purulent sputum.^{8,15} Human α -thrombin and γ -thrombin were prepared and stored at -70°C in 0.75 mol/L of NaCl at concentrations of 2 to 4 mg/mL.^{16,17} As determined by active-site titration (*p*-nitrophenyl-*p'*-guanidinobenzoate), the specific activities of the α -thrombin and γ -thrombin preparations were 95% and 78%, respectively.^{18,19} Antithrombin III was obtained as a gift from the American Red Cross Fractionation Center, Bethesda, MD. As analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE),

the inhibitor migrated as a single band; >96% of the antithrombin III formed a higher mol-wt complex with α -thrombin.

Proteolysis of α -thrombin by elastase. α -Thrombin (~10 $\mu\text{mol/L}$) was incubated with elastase (thrombin/elastase molar ratios from 1:1 to 100:1) for various times (37°C) in 0.02 mol/L of Trizma base (Tris), pH 7.4, or in Tris buffer containing 0.15 mol/L of NaCl. Incubations were performed in the presence or absence of 1 U/mL of sodium heparin (140 U/mg) from porcine intestine (Elkins-Sinn, Cherry Hill, NJ). The reaction was stopped either by incubating for 10 minutes (37°C) with 0.7 mmol/L of MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl (Enzyme Systems Products, Livermore, CA) to inhibit elastase activity²⁰ or by boiling in SDS as detailed later. Samples were quantitated for residual elastase activity with MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl (Enzyme Systems Products) as described.²¹ Only those samples demonstrating >95% inhibition of initial activity were used in the following studies.

SDS-PAGE. Samples for electrophoresis (4 to 8 μg per lane) were mixed with an equal volume of 0.06 mol/L of Tris, 2% SDS, 5% glycerol, 0.001% bromphenol blue, and 2% dithiothreitol (SDS-DTT), solubilized by heating at 100°C for 3 minutes, and stored (-70°C). SDS-PAGE was performed by the method of Laemmli,²² using a 3.8% stacking gel and a 9% to 18% gradient separation gel. Electrophoresis was terminated when the buffer front was 1 cm from the bottom of the gel. Gels were fixed in 25% isopropanol and 10%

acetic acid prior to being stained with Coomassie blue (0.1%). Densitometry was performed at 633 nm using an LKB Ultrascan Laser Densitometer and LKB model 2210 dual-channel recorder.

Mol wt markers included phosphorylase b (mol wt 94,000), bovine serum albumin (BSA) (mol wt 67,000), ovalbumin (mol wt 43,000), carbonic anhydrase (mol wt 30,000), soybean trypsin inhibitor (mol wt 20,100), α -lactalbumin (mol wt 14,400), and aprotinin (mol wt 6,500).

Interaction of elastase-modified thrombin with antithrombin III. α -Thrombin (11 μ mol/L) was incubated either alone or with elastase (1.7 μ mol/L) for 60 minutes (37 °C) in 0.02 mol/L of Tris pH 7.4 containing 1 U/mL of porcine intestinal heparin. The mixture was incubated for 10 minutes (37 °C) with 0.7 mmol/L of MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl prior to addition of antithrombin III (30 μ mol/L). Samples were taken at various times for analysis by SDS-PAGE.

Amino acid sequence of elastase-modified thrombin. Samples were prepared for sequencing as described²³ by extensive dialysis against 0.1% trifluoroacetic acid (TFA) and freeze-drying. The final thrombin product (210 μ g) was dissolved in 0.1% TFA, and one-half (2.6 nmol) was applied to a Beckman 890M spinning cup sequencer. The resultant phenylthiohydantoin (PTH) derivatives were resolved on a Beckman Ultrasphere 5- μ m ODS column using a Waters 501 pump, 440 detector (254 nm) and 740 integrating recorder. Isocratic separation of the common PTH amino acids was achieved at 55 °C with 0.01 mol/L of sodium acetate, pH 4.54 and acetonitrile (38:62, vol/vol) at a flow rate of 1 mL/min. PTH yields were automatically calculated by peak area and expressed as a percentage of the respective 200-pmol standard. Duplicate thrombin samples were subjected to sequence analysis.

Amidolytic activity. Samples of α -thrombin and elastase-treated thrombin (>95% conversion to the cleaved form on SDS-PAGE) were analyzed for amidolytic activity with Tos-Gly-Pro-Arg-paranitroanilide (GPA, Vega) by modification of the method of Kirchoff and colleagues.²⁴ GPA was dissolved in methanol (14 mg/mL). Duplicate dilutions of thrombin (0.3 to 270 nmol/L) in Tris 0.2 mol/L, pH 7.4 containing 1 mg/mL of BSA (Sigma) were incubated at 23 °C (final volume 0.2 mL per well) with GPA (0.5 mg/mL) in 96-well microtitration plates (Nunc). Color development at 405 nm was followed on a Titertek Multiscan photometer (Flow Laboratories, McLean, VA). The change in absorbance per minute was subtracted from the values obtained in wells that did not contain thrombin. Plots of color development with time demonstrated a linear relationship.

Fibrinogen clotting activity. Human fibrinogen (Kabi Grade L) was dissolved in 0.3 mol/L of NaCl, 0.1 mol/L of sodium citrate pH 6.4, containing 0.01 mol/L of ϵ -aminocaproic acid (Aldrich, Milwaukee), and stored (–70 °C). For thrombin assays, fibrinogen was diluted (6.4 mg/mL) in 10 mmol/L of imidazole, 10 mmol/L of CaCl₂, 0.15 mol/L of NaCl pH 7.4. Aliquots (0.09 mL) were prewarmed to 37 °C prior to the addition of various concentrations of thrombin prepared in 0.2 mL of the same buffer (37 °C) containing 0.1% BSA. Clotting time was determined by fibrometer (Becton Dickinson No. 60415).

Platelet stimulation studies. Washed platelet suspensions were prepared by modification of the technique of Mustard and co-workers as described.^{6,25-27} Platelet stimulation studies were performed at 37 °C with 0.45-mL aliquots of washed platelets (2×10^8 /mL) stirred at 1,000 rpm in a Chrono-Log model 460 Lumi-Dual double-channel aggregometer. Aggregation and luminescence in each channel was recorded with a Chrono-Log model 703 strip chart dual-pen recorder. Aggregation was quantitated by planimetry.²⁸ Results were expressed as percentage of the area under the control curves.

Secretion was measured by the luminescence reaction of secreted

ATP with 4 μ L of firefly luciferin and luciferase (40 mg/mL, Chrono-Lume No. 395, Chrono-Log) added 1 to 5 minutes prior to stimulation of the platelets.^{29,30} Secretion was measured as the maximum increase in fluorescence and expressed as the percentage of the increase in the control.

The threshold stimulus determined for individual platelet preparations was defined as the lowest concentration that caused $\geq 90\%$ increase in light transmission at 5 minutes when added to stirred platelets at 37 °C³⁰ and resulted in fluorescence at least 90% of maximum. Immediately after measurements of aggregation and secretion, 40 μ mol/L of ATP (Sigma FF-ATP, 1 mg/mL, and 40 mg/mL of MgSO₄ · 7 H₂O) was added for instrument calibration.

RESULTS

Incubation of α -thrombin with elastase. α -Thrombin was incubated alone or with elastase for various times (37 °C). After MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl was added to inhibit elastase activity, samples were reduced, electrophoresed, and stained with Coomassie blue. The B chain of thrombin migrated as a single band at mol wt 32,500 after incubation for 0 to 30 minutes with buffer alone (Fig 1, lanes 9 through 10). The small (mol wt) α -thrombin A chain was not visualized in this system.¹⁶ Incubation of thrombin with elastase (thrombin/elastase molar ratio 8:1) resulted in proteolysis (lanes 1 through 4). After incubation with elastase for 15 seconds, lower mol wt bands were observed (lane 1). Those at mol wt ~28,000 co-migrated with the elastase isomers³¹ seen in the elastase controls (lanes 11 and 12). New bands also appeared at mol wt 21,000, 16,000, and 15,000. These bands were diminished or absent if elastase was inactivated with α_1 -antitrypsin (experiment not shown) or with greater concentrations of MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl prior to the addition of SDS to the mixture. This suggests that these peptides may result from either (a)

Fig 1. Effect of heparin on thrombin proteolysis. α -Thrombin (10 μ mol/L) was incubated (37 °C) with elastase (1 μ mol/L) in 0.02 mol/L of Tris pH 7.4 with (lanes 1 through 4) or without (lanes 5 through 8) of heparin (1 U/mL). After various times, MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl (0.7 mmol/L) was added to inhibit elastase activity. Samples were electrophoresed (5 μ g thrombin per lane) and stained with Coomassie blue. The α -thrombin controls at 0 and 30 minutes are shown in lanes 9 and 10, respectively; those for elastase are shown in lanes 11 and 12.

elastase-proteolysis of SDS-denatured thrombin or (b) stimulation of elastase activity by SDS.³²⁻³⁴

With longer incubations (lanes 2 through 4), the concentration of thrombin B chain at mol wt 32,500 was diminished; by 30 minutes proteolysis of 50% of the thrombin B chain occurred. The three bands at mol wt 21,000, 16,000, and 15,000 were no longer apparent after 30 minutes, and two additional bands representing core fragments appeared at mol wt 18,500 and 13,500, designated fragment I (FI) and fragment II (FII), respectively. In four separate experiments, the mol wt of FI ranged from 17,000 to 18,500, and that of FII ranged from 12,000 to 13,500.

In experiments not shown, FI and FII could not be separated under nondenaturing conditions (0% to 1 mol/L of NaCl; 0% to 3% Triton X-100, Sigma, St Louis). This suggests that FI and FII are held together by strong noncovalent interactions, as reported for the γ -thrombin B chain fragmentation peptides.³⁵⁻³⁸

Heparin binds to both thrombin and elastase.³⁹⁻⁴³ Therefore, the effect of heparin on elastase-mediated proteolysis of α -thrombin was examined. α -Thrombin was incubated with elastase in Tris buffer with 1 U/mL of heparin (lanes 5 through 8). Within 15 seconds after the addition of elastase to α -thrombin, FI and FII were observed (lane 5). The breakdown products at mol wt 21,000, 16,000, and 14,000 seen in lanes 1 and 2 were not observed in the presence of heparin. Within 3 minutes (lane 6), >50% of α -thrombin was proteolyzed to FI and FII; by 30 minutes (lane 8), the conversion of α -thrombin to FI and FII was complete.

These results indicate that heparin accelerates elastase-mediated proteolysis of α -thrombin. They also suggest that heparin protects α -thrombin from conversion into the mol wt 21,000, 16,000, and 14,000 fragments.

Elastase cleavage of factor IX is less extensive in the absence of calcium.⁶ Therefore, the above experiments were performed in the presence of CaCl_2 (2 to 6 mmol/L). Calcium did not alter or inhibit proteolysis of thrombin by elastase.

When analyzed on SDS-PAGE without disulfide bond reduction, thrombin fragments FI and FII were identified at mol wt 23,000 and 13,500 (gel not shown). The increase in the mol wt of FI prior to reduction suggested that it was covalently linked to the thrombin A chain.

Interaction of elastase-modified thrombin with antithrombin III: Identification of the active-site-containing fragment. To determine if FI or FII contained the active-site serine, antithrombin III was incubated either with α -thrombin or with the elastase-modified protease in the presence of 1 U/mL of heparin (inhibitor/enzyme molar ratio ~3:1). After various times, samples were analyzed by SDS-PAGE (Fig 2). α -Thrombin incubated in the presence of elastase (lane 1) was converted into the elastase-modified form, as indicated by the presence of FI and FII. A faint band representing elastase was seen at mol wt 28,000. Lane 2 contained α -thrombin incubated in the absence of elastase for comparison, and lane 3 contained antithrombin III (mol wt 58,000). Incubation of antithrombin III with the modified thrombin for 15 seconds, 5 minutes, and 60 minutes (lane 4, 5, and 6, respectively) resulted in formation of a band at mol

Fig 2. Interaction of elastase-modified thrombin with antithrombin III. α -Thrombin (11 $\mu\text{mol/L}$) was incubated either alone or with 1.7 $\mu\text{mol/L}$ of elastase at 37 $^{\circ}\text{C}$ prior to incubation at 37 $^{\circ}\text{C}$ (10 minutes) with MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl (0.7 mmol/L). Antithrombin III (30 $\mu\text{mol/L}$) was added to the mixtures, and samples were taken for analysis at various times. Lane 1, elastase-modified α -thrombin; lane 2, α -thrombin control; lane 3, antithrombin III control; lanes 4 through 6, incubation of antithrombin III with elastase-modified thrombin shown in lane 1 for 15 seconds, 5 minutes, and 60 minutes, respectively; lanes 7 through 9, incubation of antithrombin III with α -thrombin shown in lane 2 for 15 seconds, 5 minutes, and 60 minutes, respectively; lanes 10 and 11, α -thrombin was incubated with antithrombin for 5 minutes as in lane 8 prior to the addition of elastase (1.7 $\mu\text{mol/L}$). Samples were taken at 15 seconds (lane 10) and 5 minutes (lane 11). Positions of the mol wt markers are indicated on the right.

wt 72,000, the mol wt compatible with that of a complex between antithrombin III (mol wt 58,000) and FII (mol wt 13,500). In addition, after 15-second incubation (lane 4) the intensity of free FII was diminished relative to FI; within 5 minutes of incubation (lane 5), FII was no longer apparent. These findings suggest that the active-site serine is contained within FII.

For comparison, antithrombin III was incubated with α -thrombin for 15 seconds, 5 minutes, and 60 minutes, respectively (lanes 7 through 9). The α -thrombin-antithrombin III complex was visible at mol wt 88,500. A faint band was apparent at mol wt ~72,000, with electrophoretic mobility similar to the FII-antithrombin III complex. This mol wt ~72,000 complex has been shown to be the result of degradation of the α -thrombin-antithrombin complex by free thrombin.^{44,45} The relationship of this complex to the FII-antithrombin complex remains undetermined.

These results demonstrate that antithrombin III inhibits elastase-modified thrombin by combining with the active-site serine within FII. These findings suggest that elastase cleaves the α -thrombin B chain in the vicinity of the γ -cleavage site.⁴⁶ This results in the formation of an NH₂-terminal fragment (FI), mol wt 18,000, that is disulfide linked to the thrombin A chain and a COOH-terminal fragment (FII), mol wt 13,000, containing the active-site serine.

To determine if elastase can degrade preformed α -thrombin-antithrombin complexes, thrombin was incubated with antithrombin for 5 minutes as in lane 8 prior to incubation with elastase (thrombin/elastase molar ratio 9:1). Fifteen seconds after addition of elastase (lane 10), a complex was observed at mol wt 72,000; by 5 minutes (lane 11), the α -thrombin-antithrombin complex at mol wt 88,500 was markedly reduced in intensity, and protein at mol wt 72,000 was increased. A faint band migrated at mol wt 16,000. Neither fragment F1 nor fragment FII was observed in lanes 10 or 11, and there was an increase in stained material moving just behind the buffer front. These findings suggest that elastase cleavage of the α -thrombin-antithrombin complex may differ from cleavage of free α -thrombin.

Amino acid sequence of elastase-modified thrombin. Because the thrombin samples were analyzed directly after proteolysis, at least one new amino terminal sequence was anticipated, in addition to the usual A chain and B chain sequences. Amino acid analysis confirms the presence of a new NH_2 -terminal sequence corresponding to residues 151 through 156 of the human B chain of thrombin (Table 1). Residues 1 (Asn), 4 (Lys), and 6 (Gln) are unequivocal; the yields at residues 2 (Val), 3 (Gly), and 5 (Gly) are in excess of theoretical yields, assuming that only one or two peptides exist. Further efforts are under way to resolve these components so that peptide yields and the extent, if any, of protein fragmentation at the carboxy terminal regions of the three constituent polypeptides detected there can be quantitatively determined.

Amidolytic activity of elastase-modified thrombin. Increasing concentrations of elastase-modified thrombin were added to microtitration plate wells containing GPA (Fig 3). Color generation was proportional to the concentration of enzyme in the range of 13.6 to 272 nmol/L. The amidolytic activity of the modified enzyme appeared to be nearly identical to that of α -thrombin.

Fibrinogen clotting activity of elastase-modified thrombin. The fibrinogen clotting activity of elastase-modified thrombin (>98% conversion to the modified form in the presence of heparin 1 U/mL) was compared with that of α - and γ -thrombin (Fig 4). At each thrombin concentration, the clotting time of the modified thrombin was greater than that

Fig 3. Amidolytic activity of elastase-modified thrombin. α -Thrombin [T] or elastase-modified thrombin (T_e) was diluted (0.3 to 270 nmol/L) in buffer and incubated at 23 °C with Tos-Gly-Pro-Arg-paranitroanilide (GPA) (0.5 mg/mL). Color development was analyzed as detailed in the Materials and Methods section. Each point is the average of duplicate determinations. Curves were determined by linear regression analysis. For T, $y = 39.2x - 33.2$ ($r = 0.988$); for T_e , $y = 39.7x - 41.4$ ($r = 0.968$).

of α -thrombin but less than that of γ -thrombin. As determined by comparing the slopes of the three lines obtained by linear regression analysis (Fig 4 legend), elastase-modified thrombin was 32% as potent as α -thrombin in clotting fibrinogen; γ -thrombin was 1% as potent as α -thrombin. The relative slopes of the three curves were unaltered by the presence or absence of heparin or by the addition of elastase to α -thrombin immediately prior to mixing with fibrinogen (experiments not shown).

Platelet stimulatory activity of elastase-modified thrombin. To compare the platelet-stimulatory activity of elastase-modified thrombin with that of α -thrombin and γ -

Fig 4. Fibrinogen clotting activity of elastase-modified thrombin. α -Thrombin (T), elastase-modified thrombin (T_e), or γ -thrombin (T_γ) was diluted in buffer and prewarmed to 37 °C. After fibrinogen was added (2.0 mg/mL), fibrin clotting time was determined as detailed in the Materials and Methods section. Each point represents an individual clotting time measurement. Curves were determined by linear regression analysis. For T, $y = 77.7x + 17.02$ ($r = 0.968$); for T_e , $y = 245.6x + 8.66$ ($r = 0.992$); and for T_γ , $y = 6629x + 12.44$ ($r = 0.941$). Study shown is representative of studies on four separate T_e preparations. Equivalent concentrations of T, T_e , and T_γ had similar amidolytic activities against Tos-Gly-Pro-Arg-paranitroanilide (GPA).

Table 1. Sequence of Elastase-Treated Human α -Thrombin

Cycle	Amino Acid Detected		
	A-chain	B-chain	Additional Peptide
1	Thr (0.6)	Ile (1.2)	Asn (0.8)
2	Phe (1.0)	Val (1.9)	Val (1.9)
3	Gly (1.6)	Glu (0.5)	Gly (1.6)
4	Ser (NQ)	Gly (0.7)	Lys (0.8)
5	Gly (1.4)	Ser (NQ)	Gly (1.4)
6	Glu (0.6)	Asp (0.4)	Gln (0.3)

Human α -thrombin (2.6 nmol) was subjected to sequence analysis. Yields (in parentheses) are corrected to final yield, expressed in nanomoles. The sequence, Additional Peptide, corresponds to residues 151 through 156 of the human thrombin B-chain.

Thr, threonine; Ile, isoleucine; Asn, asparagine; Phe, phenylalanine; Val, valine; Gly, glycine; Glu, glutamic acid; Ser, serine; Lys, lysine; Gln, glutamine, NQ, not quantitated.

Fig 5. Platelet stimulation by elastase-modified thrombin. Washed platelets (2×10^8 /mL) were stirred in the presence of luciferin and luciferase for 1 minute at 37 °C prior to the addition of elastase-modified thrombin (T_e), α -thrombin (T), or γ -thrombin (T_γ , inset). Aggregation was recorded as the increase in light transmission and quantitated by planimetry. Results were expressed as percentage of the area under the control curves. Secretion was expressed as the maximum increase in fluorescence expressed as a percentage of the increase in the control. Equivalent concentrations of T , T_e and T_γ had similar amidolytic activity against Tos-Gly-Pro-Arg-paranitroanilide (GPA).

thrombin, platelet aggregation and secretion were measured simultaneously with a lumi-aggregometer. Examples of standard curves of α -thrombin-induced platelet aggregation and ATP-mediated luminescence are shown in Fig 5. The concentration of α -thrombin required to liberate 50% of maximally releasable ATP from platelets was 1.1 nmol/L. This was similar to the concentration required to cause 50% of maximal aggregation. In contrast, the concentration of modified thrombin required to liberate 50% of releasable ATP and to cause 50% of maximal aggregation was ~7.9 nmol/L. As a result, both curves representing aggregation and secretion were shifted to the right. Using the concentration required to produce 50% maximal stimulation for comparison, the modified thrombin was ~14% as potent as α -thrombin in stimulating both platelet aggregation and platelet release. In three additional experiments using three different preparations of the modified thrombin, the modified thrombin was 10% to 19% as potent as α -thrombin.

γ -Thrombin was a less potent platelet stimulus than elastase-modified thrombin (Fig 5 inset). The concentration required to cause 50% of maximum platelet aggregation and release was ~220 nmol/L (0.5% as potent as α -thrombin).

Elastase has been reported to inhibit thrombin-induced platelet aggregation and secretion.⁹ The final concentration of elastase in the cuvette (≤ 3.5 nmol/L), however, was less than that required to inhibit platelet function in this system.⁹ In addition, incubation of similar concentrations of chloromethyl ketone inhibited elastase (95% inhibited by MeO-Suc-Ala-Ala-Pro-Val-CH₂Cl) with α -thrombin (0 to 60 minutes) did not inhibit thrombin-induced platelet aggregation or secretion.

DISCUSSION

These studies demonstrate that human α -thrombin, upon proteolysis by PMN elastase, exhibits diminished fibrinogen

clotting activity and diminished platelet stimulatory activity, as measured by platelet aggregation and platelet ATP release. Loss of α -thrombin function is associated with limited cleavage of the thrombin B chain.

The concentration of prothrombin in plasma is sufficient to generate ~150 U/mL of α -thrombin.^{46,47} In addition to being inactivated by circulating inhibitors, α -thrombin selectively binds to fibrin, thereby becoming less susceptible to inactivation by its plasma inhibitors.⁴⁸⁻⁵⁰ These studies suggest that fibrin acts as a reservoir for enzymatically active thrombin. Human PMNs release elastase as blood clots^{2,3}; in addition, PMNs penetrate preformed blood clots, accumulate within thrombin, and ingest fibrin.⁵¹⁻⁵³ Recently, Weitz and co-workers documented that the fibrinogen peptide A α 1-21 is a specific in vivo indicator of elastase-mediated proteolysis of fibrinogen and higher levels of A α 1-21 were found in patients with α_1 -antiprotease deficiency than in healthy controls.⁵⁴ In a similar manner, the limited digestion of α -thrombin by elastase could be an important physiologic mechanism for regulation of the activity of both free and fibrin-bound thrombin.

PMN elastase cleaves the thrombin B chain at Ala 150-Asn 151. This site is four amino acids to the NH₂-terminal side of the autoproteolytic or tryptic γ -thrombin cleavage site; the β domain is not cleaved. Proteolysis by PMN elastase occurs in areas rich in apolar amino acids.^{32,55-57} In contrast to the positively charged thrombin β cleavage domain, the γ cleavage site (Lys 154-Gly 155) resides within a domain containing several apolar amino acids.³⁶⁻³⁸ This area should be susceptible to cleavage by elastase.^{32,55-57} These considerations are compatible with our findings that the larger NH₂-terminal fragment, FI (mol wt ~18,000) is disulfide linked to the thrombin A chain; and the smaller COOH-terminal fragment, FII (mol wt ~13,000) contains the active-site serine, as indicated by the recovery of a covalent bond between FII and antithrombin III. These results are supported by the recent report that porcine pancreatic elastase also cleaves a single peptide linkage in prothrombin corresponding to Ala 150-Asn 151 within the α -thrombin B chain, thereby facilitating localization of the staphylocoagulase-binding region to the COOH-terminal fragment.⁵⁸

PMN elastase binds to glycosaminoglycans of biologic importance, including heparin, heparin sulfate, dermatan sulfate, chondroitin sulfate, and hyaluronic acid.⁴³ Although glycosaminoglycans inhibit the amidolytic activity of elastase against a small oligopeptide substrate,⁴³ heparin stimulates elastase-mediated proteolysis of elastin.⁵⁹ Thus, our finding that heparin accelerates elastase-mediated proteolysis of α -thrombin is not without precedent. It also suggests that the physiologic interaction of elastase with thrombin might be a surface-mediated phenomenon. Finally, because heparin binds to both thrombin and elastase,^{43,60} a template mechanism similar to that for the thrombin-antithrombin III reaction is implied, whereby the interaction of both thrombin and elastase with heparin are involved in the expression of catalytic activity.⁶²⁻⁶³

Elastase-modified thrombin might be an important probe of the thrombin γ cleavage domain. In marked contrast to

autolytic or tryptic digestion of α -thrombin,^{16,44} elastase-mediated proteolysis of the γ region does not require proteolysis near the β cleavage site prior to cleavage in the γ region. Cleavage at the β site reduces fibrinogen clotting activity.⁶⁴⁻⁶⁷ Therefore, it is not surprising that the elastase-modified enzyme, with an intact β domain, retains some fibrinogen clotting activity. Likewise, we found (Fig 5) that the platelet stimulatory activity of elastase-modified thrombin (14% that of α -thrombin) is greater than that of γ -thrombin (0.5% that of α -thrombin). These findings, confirming the results of others for human γ -thrombin,⁶⁸ suggest

that thrombin-induced fibrinogen clotting and platelet stimulation are altered by cleavage near the γ cleavage site. In contrast, cleavage near the γ cleavage site does not appear to inhibit inactivation by antithrombin III.⁶⁹ The limited digest of α -thrombin by elastase should prove useful in the investigation of the structure and function of human thrombin.

Variability of the Erythropoietic Response in Autoimmune Hemolytic Anemia: Analysis of 109 Cases

By Jane L. Liesveld, Jacob M. Rowe, and Marshall A. Lichtman

One hundred-nine cases of autoimmune hemolysis were reviewed to determine the frequency of reticulocytopenia, the state of the erythroid marrow in reticulocytopenic cases, and the course of reticulocyte production indices with time and glucocorticoid treatment. The mean hematocrit at presentation was 24 mL/dL, but 30% of cases had an initial hematocrit <20 mL/dL. Median reticulocyte percentage at diagnosis was 9%, and median reticulocyte production index was 2.8 times basal. Twenty percent of cases had an initial reticulocyte count <4%, and 37% had an initial reticulocyte production index <2.0 times basal. These reticulocytopenic patients were nearly evenly distributed between warm and cold antibody-mediated cases and between primary and secondary cases. Fifty-four percent of reticulocytopenic cases had a bone marrow examination during hospitalization. Three-fourths of these marrows showed erythroid hyperplasia, and erythroid hypoplasia was seen in only one case. Eighty-eight cases

had serial reticulocyte measurements, and in only 15% of patients did the reticulocyte production index remain <2.0 times basal. Thus, in most cases, the initially low reticulocyte production index may represent a lag in marrow responsiveness to hemolytic stress. In cases with persistent reticulocytopenia, ineffective erythropoiesis is suggested by the frequency of marrow erythroid hyperplasia. In the cases that were initially reticulocytopenic and demonstrated an increase in reticulocyte production index, the magnitude of this increase was significantly greater in glucocorticoid-treated patients than in those not so treated, indicating that a glucocorticoid sensitive component exists in the marrow erythropoietic response to hemolysis. Awareness of the frequency of an initial reticulocytopenia in cases of autoimmune hemolysis may be important in initial diagnosis and treatment.

AUTOIMMUNE hemolytic anemia has a wide spectrum of expression.^{1,2} Its onset can be abrupt and severe and can lead to a rapid and profound decrease in the hemoglobin concentration, which in elderly or chronically ill patients can result in death. In other subjects, RBC sensitization with antibody may not be associated with clinically evident hemolysis. This wide variability in the degree of shortening of RBC survival is further complicated by the variability in the response of the erythroid marrow to anemia. In most cases, a good reticulocyte response occurs and, in some cases, the combination of severe hemolysis and a brisk marrow response can lead to a situation in which all or nearly all of the erythrocytes in the blood are reticulocytes. The erythroid response, however, can be inappropriately low, and several reports or series²⁻²² have highlighted cases that have been associated with reticulocytopenia.

In these studies, we have defined more formally the erythropoietic response of patients with autoimmune hemolytic anemia to determine the frequency of reticulocytopenia, the state of the erythroid marrow in the reticulocytopenic patient, and the effects of time and glucocorticoid treatment on the reticulocyte response. Associated blood cell changes,

including the frequency of neutropenia and neutrophilia, of lymphopenia and lymphocytosis, and of thrombocytopenia and thrombocytosis are also presented.

MATERIALS AND METHODS

The medical records of 109 consecutive cases of autoimmune hemolysis at two University of Rochester hospitals (Strong Memorial Hospital and St Mary's Hospital) from 1965 to 1985 were reviewed. Charts were located by means of a computerized numerical diagnosis coding system. Criteria for inclusion as a case of autoimmune hemolysis were (a) a positive direct Coombs' test with anemia or clinical evidence for hemolysis or (b) a clinical diagnosis of autoimmune hemolytic anemia with elevated cold agglutinin titers in cases in which complete serologic test results were not available in the record (three cases). One case with a clinical diagnosis of Coombs' negative autoimmune hemolytic anemia was also included.

Age at diagnosis, year of presentation, sex, race, Coombs' test results, and hematocrit at presentation were recorded for all 109 patients. Initial reticulocyte counts were available in 108 cases. Other information recorded when available included the second, highest, lowest, and last reticulocyte counts during the hospital admission (88 patients), lowest and last hematocrit, first WBC count and WBC differential count, first platelet count, first mean corpuscular volume (MCV), first serum lactic dehydrogenase (LDH), and first total and direct bilirubin measurements. The description of the marrow aspirate and biopsy was recorded when available. Historical information obtained included associated illnesses, treatment administered, and number of transfusions. Cases were classified according to the following hemolysis subtypes: primary warm antibody, primary cold antibody, secondary warm antibody, secondary cold antibody, and drug-induced antibody.

Adjustments of the reticulocyte count for hematocrit (corrected reticulocyte count) and for determination of reticulocyte production index (RPI) were made.²³ Tests of statistical significance between group means or frequencies were done with Student's *t* test or chi-square test, respectively.²⁴ The microcoombs' test was performed using the antiglobulin consumption technique.²⁵ Serum LDH and bilirubin were determined using standard laboratory procedures. Indirect bilirubin was calculated as the difference between total and direct bilirubin measurements. Group data are expressed as the mean $\pm$ 1 SD unless otherwise specified.

RESULTS

Patient Characteristics and Type of Hemolytic Antibody

One hundred-four of the 109 cases in this study were diagnosed while they were inpatients. Patients ranged in age from 4 months to 91 years. Seventy-one of the cases (65%) were female, and 38 were male (35%). Ninety-five percent of the patients were white and 5% were black.

Categories of hemolysis. Table 1 summarizes the frequency of hemolysis types identified by serologic and clinical studies. Nine of the drug-induced cases were associated with α -methyl dopa²⁶ and one with procainamide.²⁷ Three cases were not classifiable into one of these categories: One case had mixed features (warm and cold antibodies) and one case was direct Coombs' negative; in one case, the direct Coombs' test was positive but the γ and complement Coombs' reagent results were lost from the record. Four cases in this series had positive microcoombs' tests; ie, >40 molecules IgG per cell, when the direct Coombs' test was negative.

Presenting Hematocrits and Reticulocyte Counts

Hematocrit. At the time of diagnosis, the median hematocrit of patients was 24 mL/dL; range 9 to 56 mL/dL. The patient with the initial hematocrit of 56 mL/dL had severe chronic obstructive lung disease and cor pulmonale with higher baseline hematocrits. Figure 1 shows the cumulative frequency curve of presenting hematocrits.

Reticulocyte counts. The median reticulocyte percentage of patients at their presentation was 9% (range 0.4% to 92%). The mean reticulocyte count corrected to a hematocrit of 45 mL/dL (corrected reticulocyte count) was 7.4 ± 7.3 (median 5, range 0.1 to 45). The mean RPI was 3.8 ± 3.5 times basal (median 2.8, range 0.06 to 19 times basal). Figure 2 shows the cumulative frequency curve of the initial reticulocyte measurements. Reticulocyte counts were available in 108 of 109 patients. In the remaining case, the blood smear showed marked polychromatophilia, but this patient was excluded from analyses involving reticulocyte quantification. In the 88 cases in which serial reticulocyte counts were available, the first reticulocyte count was strongly correlated with the second reticulocyte count ($r = .87$, $P < .0001$). In 80% of cases with serial reticulocyte values available, the second reticulocyte count was obtained within 3 days of the first count.

By linear regression analysis, the reticulocyte percentage was significantly inversely correlated with the presenting

Fig 1. The cumulative percentage of hematocrits obtained at diagnosis in 109 cases. Median hematocrit was 24 mL/dL, and 30% of cases had an initial hematocrit of ≤ 20 mL/dL.

hematocrit ($r = -.35$, $P < .001$), although the correlation was weak. The corrected reticulocyte percentage and RPI did not correlate significantly with presenting hematocrit. Table 1 shows the mean presenting hematocrits and reticulocyte values based on the type of hemolysis. Although primary cold antibody-mediated hemolysis cases had a higher mean hematocrit and lower reticulocyte production index, the sample size was too small to reach conclusions regarding the significance of these differences.

Initial WBC and Platelet Counts

WBC counts were obtained in 108 patients. The mean WBC was $10,602 \pm 6,571$ cells/ μ L with a median of 9,000 cells/ μ L. The range was 1,500 to 137,000 cells/ μ L. Three WBC values $\geq 30,000$ cells/ μ L were excluded when the mean was calculated. Each of these three values occurred in a case of chronic lymphocytic leukemia. Median WBC counts were normal in both primary and secondary cases of warm hemolysis but were elevated in the primary and secondary cold antibody groups; 11,250 and 12,900 cells/ μ L, respectively.

Thirteen percent of cases had a decreased total WBC ($< 4,500$ cells/ μ L), and $\sim 40\%$ of all patients had an elevated total WBC ($> 11,000$ cells/ μ L). All 14 cases with leukopenia at diagnosis had warm antibody-mediated hemolysis and were equally divided between primary and secondary types. Mean hematocrit in the leukopenic group was 25 ± 8.6 mL/dL (median 23 mL/dL), and mean RPI was 2.9 ± 2.0 times basal (median 2.5). Six of the 14 cases with leukopenia

Table 1. First Hematocrit and Reticulocyte Count According to Type of Hemolysis

Hemolysis Type	Frequency of Cases (%)	(n)	Hematocrit (mL/dL)	Reticulocyte Count (%)	Reticulocyte Production Index ($\times$ Basal)
Primary warm antibody	47	51	$25 \pm 8.6(23)$	$18 \pm 20(10)$	$4.3 \pm 4.4(3)$
Secondary warm antibody	22	24	$25 \pm 9.4(24)$	$14 \pm 12(9)$	$3.4 \pm 2.1(3)$
Primary cold antibody	7	8	$32 \pm 11(30)$	$9.6 \pm 11(4)$	$3.0 \pm 2.8(2)$
Secondary cold antibody	12	13	$26 \pm 7.4(26)$	$11 \pm 7.1(8)$	$3.2 \pm 2.3(2)$
Drug-induced	9	10	$28 \pm 6.2(29)$	$13 \pm 10(10)$	$3.9 \pm 3.0(3)$
Unclassified	3	3	22	3.6	.85
All cases	100	109	$26 \pm 8.8(24)$	$15 \pm 16(9)$	$3.8 \pm 3.5(3)$

Data are presented as the mean $\pm$ SD. Median values are shown in parentheses. Medians and SD are not shown for the three unclassified cases.

Fig 2. The cumulative percentage of first uncorrected reticulocyte percentage count obtained at diagnosis in 108 cases. Approximately 20% of patients had an initial reticulocyte count $<4\%$.

also had platelet counts $<120,000/\mu\text{L}$, and one other case developed thrombocytopenia later. Seven of the 14 had a palpable spleen, and one had splenic enlargement by radio-nuclide scan. None of the cases with leukopenia had received myelosuppressive drugs, and none had marrow infiltrative disease.

Of the patients with leukocytosis at presentation, approximately one-third had cold antibody-mediated hemolysis. Forty percent of these cases had initial reticulocyte production indices ≤ 2.0 times basal, but none had thrombocytopenia. Mean hematocrit in this group was $23 \pm 9.2 \text{ mL/dL}$. Figure 3A shows the cumulative frequency of the neutrophil count; Fig 3B shows the cumulative frequency of the lymphocyte count.

Initial platelet counts were available in 85 patients. An additional 19 patients had normal platelet estimates. Mean initial platelet counts did not differ significantly between subjects with warm antibody-induced or cold antibody-induced hemolysis. Figure 4 shows the cumulative frequency of initial platelet counts. Each of the 13 cases with thrombocytopenia at presentation was warm antibody-mediated, and these were divided approximately equally between primary and secondary types. Six of these cases had been given a clinical diagnosis of idiopathic thrombocytopenic purpura. One patient had chronic lymphocytic leukemia, and one had lymphoma with marrow involvement. Mean hematocrit in patients with thrombocytopenia was $30 \pm 7.6 \text{ mL/dL}$ (median 32), and mean RPI was 2.6 ± 1.5 times basal (median 2). In the 16 cases with thrombocytosis, 13 were warm antibody-mediated cases, two were secondary cold antibody-mediated cases in young adults, and one was a mixed warm-and cold-mediated case—also in a pediatric patient. Twelve of these 16 cases with thrombocytosis had a total WBC $>11,000 \text{ cells}/\mu\text{L}$. Mean hematocrit in those cases with thrombocytosis was $21.3 \pm 6.4 \text{ mL/dL}$ (median 21), and mean RPI was 3.9 ± 4.6 times basal (median 2.4).

Effect of Glucocorticoid Treatment on Reticulocyte Count

Serial reticulocyte counts were available in 88 cases. Glucocorticoids were used in 65 of these 88 cases (Table 2).

Fig 3. (A) Cumulative percentage of absolute neutrophil counts based on first WBC differential count obtained in 102 cases. Approximately 40% of cases had an absolute neutrophil count $>7,000/\mu\text{L}$. (B) Cumulative percentage of absolute lymphocyte count based on first WBC differential count in 102 cases. Eighteen patients had an absolute lymphocytosis $>4,000/\mu\text{L}$. Four patients had chronic lymphocytic leukemia, and five had cold antibody-mediated hemolysis.

Thirty-nine of these 65 cases had an increase in RPI while on steroids; in the other 26, the production index either remained stable or decreased. As summarized in Table 2, those who demonstrated an increase in reticulocyte production index while on steroids had lower mean initial hematocrits and RPIs than did those without such reticulocyte response. The magnitude of the increase in RPI in response

Fig 4. Cumulative percentage of initial platelet counts in 85 cases. Eighteen percent of patients had a platelet count $<120,000/\mu\text{L}$ and $\sim 20\%$ had a platelet count $>400,000/\mu\text{L}$.

Table 2. Effect of Glucocorticoid Treatment on RPI

Glucocorticoids	Effect on Reticulocyte Index	No. of Cases	Hct on Day of Initial RPI	Initial Reticulocyte Index	Highest Reticulocyte Index
Administered	Increase	39	22 ± 5.7	3.5 ± 2.9	7.2 ± 4.3
	No increase	26	26 ± 8.1	6.1 ± 5.2	—
None	Increase	14	23 ± 7.2	1.5 ± .93	3.8 ± 1.8
	No increase	9	30 ± 6.6	4.1 ± 5.6	—

RPI, reticulocyte production index; Hct, hematocrit.

Total cases = 88 with serial reticulocyte measurement available; data presented as mean ± SD.

to steroids (3.5 to 7.2 times basal) was significant as measured by the paired *t* test ($P < .01$). Seventy-five percent of cases reached their maximum RPI by 6 days after the initiation of glucocorticoid treatment, which represented the tenth day of hospitalization.

Fourteen of the 23 patients not treated with glucocorticoids also had an increase in their RPI. This mean increase (1.5 to 3.8 times basal) was also statistically significant ($P < .01$). Seventy-five percent of untreated cases attained their maximum increase in RPI by 10 days of hospitalization.

Analysis of Features in Cases Presenting With Low RPI

Figure 5 depicts the cumulative percentage graph of the initial RPI. Forty (37%) of the 108 cases with reticulocyte counts initially had an RPI of ≤ 2.0 times basal. About 30% of those with primary warm antibody-mediated disease, 30% with secondary warm antibody-mediated disease, 50% with primary cold antibody-mediated disease, 50% with secondary cold antibody-mediated disease, and 30% with drug-induced disease had an initial RPI ≤ 2.0 times basal. The higher percentage found in cases of cold antibody-mediated as compared with warm antibody-mediated hemolysis was not significantly different by chi-square test. A higher pro-

portion of the group with an RPI ≤ 2.0 was transfused (53% v 38%), and a lower proportion received steroids (65% v 87%), although these differences were not statistically significant by chi-square test. Mean hematocrit, platelet count, WBC, and serum LDH did not differ significantly between the two groups. The mean indirect bilirubin was significantly higher (3.3 ± 2 v 2.1 ± 1 mg/dL) in those with production indices ≤ 2 times basal, perhaps a reflection of both hemolysis and ineffective erythropoiesis.

As noted previously and in Table 2, 53 of 88 cases with serial reticulocyte values had an increase in RPI during hospitalization; in the other 35 cases, the index remained stable or decreased. As shown in Fig 6, 13 (15%) of the 88 cases had a maximum RPI that was ≤ 2.0 times basal, indicating persistent reticulocytopenia during hospitalization. Fifty-four percent of the 13 cases with persistently low reticulocyte values received steroids.

In 33 of 40 cases with initial RPI ≤ 2.0 , serial reticulocyte values were available. Twenty-five of the 33 or 76% had increases in RPI (1.2 to 4.1 times basal) ($P < .01$). In 15 of these patients who received glucocorticoids, this increase was more substantial (3.9 ± 3.6 times basal v 2.3 ± 2.0) than in those ten not receiving steroids ($P < .01$). Seventy-five

Fig 5. Cumulative percentage of 108 cases with a given reticulocyte production index (RPI) at presentation. Production index was calculated based on initial reticulocyte percentage and hematocrit values on the same day as described in the Materials and Methods section. Thirty-seven percent of cases had an initial production index ≤ 2.0 times basal.

Fig 6. Comparison of cumulative percentage of the initial and peak reticulocyte production indices in the 88 patients in whom serial reticulocyte values were obtained. Although 37% of patients had a reticulocyte index ≤ 2.0 times basal initially, only 15% did not reach a reticulocyte index > 2.0 during serial observations.

percent of those receiving steroids had their highest RPI within 8 days of starting the hormone, which represented the twelfth hospital day. In the eight cases with an initial RPI ≤ 2.0 without a measured increase in reticulocyte production, 50% had received steroids.

Of the 55 cases with initial RPI > 2 and serial reticulocyte values, 28 (51%) had further increases in reticulocyte values during hospitalization. This increase was significant (4.6 v 8.1 times basal) as measured by paired *t* test, and all but one of these 28 patients were treated with steroids. Seventy-five percent of these patients had attained their highest RPI by the tenth hospital day, and in 75% this occurred within 5 days of starting steroid treatment. Twenty-two of the 27 cases with initial RPI > 2 who had no rise in RPI had received steroids.

A marrow aspirate or biopsy was performed in 21 of the 40 patients with RPI ≤ 2.0 (Table 3). Sixteen (76%) of these cases had erythroid hyperplasia. Only one patient had erythroid hypoplasia. Three patients had marrow involvement with lymphoma or leukemia.

Thirty-six of 68 cases diagnosed with an RPI > 2 had a marrow examination. Thirty-three (92%) had erythroid hyperplasia. In the other three cases, erythroid activity was not reported. One of these three cases showed marrow infiltration of small lymphocytes compatible with chronic lymphocytic leukemia, and another showed infiltration with breast carcinoma cells.

DISCUSSION

This series of cases of autoimmune hemolytic anemia shares many characteristics with prior reported series, including an ~70% incidence of warm antibody-mediated cases—excluding drug-induced cases,⁹ an age range extending from months to the tenth decade,^{2,9} and a case ratio of female to male of ~2:1.^{8,28} The spectrum of associated malignant and immunologic diseases is also similar to that found in prior series.^{2,9}

Although a wide range of both initial hematocrits and reticulocyte counts occurs in patients with autoimmune hemolysis, $>50\%$ of cases are diagnosed with hematocrit levels <25 mL/dL. The wide range of reticulocyte values at diagnosis and the weak inverse correlation of initial reticulocyte percentage to hematocrit confirm that the range and severity of anemia reflect several interacting variables, including the rate of hemolysis, the degree of marrow response to the hemolytic anemia, and the duration of the anemia.

The presentation of a significant proportion of patients with reticulocyte counts that do not suggest a marrow

response to hemolysis could lead to misdiagnosis of a hypoproliferative anemia or a missed diagnosis of immune hemolytic anemia if a Coombs' test is not obtained. Reticulocytopenia may contribute to the decision to transfuse or to withhold glucocorticoids more frequently in individual cases, a tendency that was noted in this series.

The subsequent increase in reticulocyte index in most patients who initially had reticulocytopenia is compatible with a more lengthy time dependency in their marrow response to hemolysis. The increase in reticulocyte index during hospitalization occurred as frequently in patients treated with glucocorticoids as in those not so treated. Pirofsky^{2,12} found that reticulocytosis usually occurred in patients with initially low reticulocyte counts with steroid therapy; however, no nontreated comparison group was reported in that series. In our study, glucocorticoid treatment did not seem to shorten the time to peak reticulocyte count in treated patients as compared with untreated patients. The difference in the peak reticulocytosis in glucocorticoid-treated patients as compared with untreated patients may indicate that the marrow response has a steroid-sensitive component as well. Glucocorticoid-treated patients had a peak reticulocyte index during serial study nearly twice that of untreated patients. A firm conclusion, however, cannot be drawn because this was not a prospective randomized study, and there may have been unidentified differences in the glucocorticoid-treated and untreated groups.

It is difficult to ascertain the prevalence of reticulocytopenia in autoimmune hemolysis from prior reports because patients in those studies were selected for type of hemolysis (warm v cold or primary v secondary), and reticulocyte production indices were not provided and reticulocyte values were not compared with hematocrit in individual cases. Allgood and Chaplin⁸ found that five of 47 idiopathic warm antibody-mediated cases had reticulocyte values $<5\%$. In their review, Crosby and Rappaport⁵ showed that 15 of 31 idiopathic cases were reticulocytopenic, as were 12 of 23 secondary cases. This series was based on case files from the Armed Forces Institute of Pathology, and the authors believed that the series selected for severe cases. Pirofsky² reported that 49% of reticulocyte counts were $<2\%$ in a group of 195 warm antibody-mediated cases. Pirofsky's series included cases with positive antiglobulin tests without documentation of hemolysis as well as cases of autoimmune hemolysis, and it contained a high proportion of secondary cases (82%). Twenty-six percent of idiopathic cases and ~50% of secondary cases had reticulocyte counts $<2\%$. In secondary cases, low counts were not related to chemotherapy or marrow infiltration.

Several mechanisms for reticulocytopenia in autoimmune

Table 3. Marrow Erythroid Cellularity in Patients With Higher and Lower Reticulocyte Counts

Reticulocyte Index	No. of Patients	Erythroid Hyperplasia	Erythroid Hypoplasia	Infiltrative Marrow Disease	Erythropoiesis Not Described
≤ 2.0	21	16(76%)	1	3	1
> 2.0	36	33(92%)	0	2	1

Fifty-seven of 108 patients with reticulocyte counts had a marrow examination. Of the 40 patients with a reticulocyte index ≤ 2 , 21 (53%) had a marrow examination. Of the 68 other patients who had a reticulocyte index > 2 , 36 (53%) had a marrow examination. The patient with erythroid hypoplasia had systemic lupus erythematosus.

hemolytic disease have been proposed. Some series have contained rare or infrequent cases with marrow aplasia, marrow infiltration, or megaloblastic changes.^{2,8} In a case of autoimmune hemolysis and marrow erythroid hypoplasia, an autoantibody distinct from the autoantibody against mature RBCs that was inhibitory to marrow erythroid colony-forming units (CFU-E) was demonstrated.²⁰ Some reports have described cases with marrow aplasia and prolonged reticulocytopenia,^{3,4,6,7,16,20} others described episodic RBC aplasia,¹⁵ and still others described transient marrow aplasia with reticulocytopenia, especially in childhood, possibly related to viral infections.^{10,11,22} Circumstances providing a clear-cut explanation for the poor erythroid response (ie, erythroid aplasia, tumor replacement of marrow, folate deficiency, or infection) are rare.

Marrow erythroid hyperplasia in reticulocytopenic cases of autoimmune hemolysis is also well described,^{2,5,13,17-19,21} and these cases comprise a far larger proportion of reticulocytopenic cases, as shown by our series. Cases of autoimmune hemolytic anemia, reticulocytopenia, erythroid cells in the marrow, but with inhibition of marrow erythroid colonies by patient plasma in vitro,¹⁹ and cases with retention of radioactive iron in the marrow and not in circulating RBCs²⁹ suggest that ineffective erythropoiesis can occur. The active erythroid marrow in the reticulocytopenic cases in our report is compatible with ineffective erythropoiesis.

The wide variability in initial WBC and platelet counts that occurs in autoimmune hemolytic anemia is also sugges-

tive of a wide range of marrow output response to the anemia and the "stress" state. Most cases of leukocytosis could not be explained by an underlying disease. The frequent coupling of leukocytosis and thrombocytosis in individual cases suggests a trilineage marrow production increase, even though in some of these cases, an appropriate reticulocyte response was not mounted. (Theoretically, this finding could be compatible with competition among lineages for stem cell differentiation commitments). The percentage of cases diagnosed with leukocytosis tended to be greater in patients with cold antibody-mediated hemolysis. Cases of leukopenia or thrombocytopenia occurred only in warm antibody-mediated cases, and underlying disease or splenomegaly did not usually account for these depressions of cell counts. The frequent coupling of leukopenia and thrombocytopenia is compatible with multiple lineage immune destruction in these cases, as first suggested by Evans and Duane in cases with prominent thrombocytopenia.³⁰

This series confirms and quantifies the wide range in the severity of anemia and in the marrow hematopoietic response to hemolysis in cases of autoimmune RBC destruction at the time of diagnosis. The significant proportion of cases diagnosed with reticulocytopenia has pathogenetic implications. Awareness of this occurrence is important to enhance prompt and accurate diagnosis and proper therapy.

Multilineage Synergistic Activity Produced by a Murine Adherent Marrow Cell Line

By Peter Quesenberry, Zengxuan Song, Elizabeth McGrath, Ian McNiece, Richard Shadduck, Abdul Waheed, Gwen Baber, Ellen Kleeman, and Donald Kaiser

We reported previously that a cell line (TC-1) derived from adherent marrow cells produced colony-stimulating factor 1 (CSF-1) and a separate activity that acts synergistically with CSF-1 to stimulate giant macrophage colonies. We now report that an activity in TC-1 conditioned media (CM) separate from CSF-1 also synergizes multilineage colony formation by pure interleukin 3 (IL 3) and a crude source of granulocyte-macrophage colony-stimulating activity (GM-CSA) (murine lung-conditioned media). IL 3-induced megakaryocyte colony formation is also synergized. The CSF-1-dependent synergistic activity is not blocked by antibodies to IL 3 and is characterized as a nondialyzable (mol wt cutoff 3,000), heat-stable (56 °C, 30') activity that binds to DE-52 cellulose under conditions in which IL 3 does

not. This material has an apparent mol wt of ~200,000 by Sephadex G100 chromatography, and the bulk of it binds to Concanavalin A (Con A) and elutes off with α -methyl mannoside, indicating that it is a glycoprotein. As reported separately, these purified active fractions also have a pre-B cell-inducing activity. In addition, a non-IL 3 activity stimulates proliferation of the factor-dependent cell lines FDC-P1 and DA-1. These data indicate that an adherent marrow cell line produces a growth factor(s) that synergizes with IL 3, GM-CSA, and CSF-1 and induces pre-B cell formation. This may be an important regulator of early multilineage lymphohemopoiesis.

© 1987 by Grune & Stratton, Inc.

PREVIOUSLY WE reported that a cell line (TC-1) isolated by differential trypsinization from the adherent cells present in long-term murine marrow liquid cultures produced colony stimulating factor 1 (CSF-1)¹ and a separate factor that did not have intrinsic colony-stimulating activity (CSA) but that synergized with CSF-1 to give rise to giant macrophage colonies.² Other researchers have reported on two separate activities that synergize with CSF-1: interleukin 3 (IL 3) and hemopoietin 1.³⁻⁵ IL 3 stimulates a wide range of colonies⁶ and thus differs from activity present in TC-1-conditioned media (CM). Hemopoietin-1, however, has no apparent intrinsic CSA and in this regard is similar to the TC-1 synergistic activity. In the present studies, we present biochemical, immunologic, and functional data indicating that the TC-1-derived synergistic activity is different from IL 3 or hemopoietin-1. In addition, we previously showed that crude CM (containing CSF-1) synergizes with IL 3 to stimulate giant mixed granulocyte-macrophage (GM)-megakaryocyte colonies. In this article, we extend those observations and demonstrate that the IL 3 synergy is not due to CSF-1. We show further that this activity potentiates a GM-CSA effect on bone marrow and stimulates the factor-dependent cell lines DA-1 and FDC-P1.⁷

MATERIALS AND METHODS

Cell Lines

TC-1 cell line. The TC-1 cell line, initially derived from C57B1/6J murine marrow,² was maintained in Fischer's media supplemented with 20% fetal calf serum (FCS), penicillin, and streptomycin. The cultures were incubated at 33 °C in 5% CO₂ and trypsinized (0.1%) and passaged every 4 to 7 days. CM were collected, centrifuged at 1,500 g, filtered through a 0.45- μ m Millipore membrane, and stored at -20 °C.

Factor-dependent cell lines. FDC-P1 cells⁷ (courtesy of Dr Jim Ihle, Frederick, MD) were grown in RPMI 1640 (GIBCO, Grand Island, NY) with 10% FCS and 25% CM from the WEHI cell line (courtesy of Dr Jim Ihle). The cells were incubated at 37 °C and 5% CO₂ in 25-cm² Corning flasks. Flasks were inoculated with 2×10^5 cells/mL and split 1:10 twice a week. DA-1 cells (courtesy of Dr Jim Ihle) were handled in a similar fashion.

Isolation of TC-1 CM-responsive FD cell lines. FDC-P1 cells were cloned in a soft-agar McCoy's clonal culture system (as used

for murine marrow colony-forming assays)⁸ (described later), in the presence of 10% to 20% 10 $\times$ TC-1 CM or 6% TC-1 CM partially purified by diethylaminoethanol (DEAE) chromatography. FDC-P1 colonies that formed after 14 and 24 days of growth were aspirated with a microliter pipette and dispersed in 35-mm Petri dishes containing 2 mL of RPMI 1640, 10% FCS, and 50% TC-1 CM. After 3 days, the cells were transferred to 60-mm Petri dishes (5 mL) and 3 days later were transferred to 25-cm² Corning flasks at 2×10^5 cells/mL. The cells were then split 1:5 to 1:10 twice weekly with reseeding kept at 2×10^5 cells/mL. After 2 weeks, cells were maintained in RPMI, 10% FCS, with 25% TC-1 CM.

Growth Factor Assays

Clonal agar assays. Marrow cells from tibias and femurs of normal ICR (Dominion Labs, Dublin, VA) or normal BDF₁ (Jackson Labs, Bar Harbor, ME) mice, aged 11 to 16 weeks, or BDF₁ mice given 150 mg/kg 5-fluorouracil (5-FU) intravenously (IV) 3 days prior to being killed were used as assay target cells. Alternatively, the factor-dependent cells FDC-P1 and DA-1 were used as assay cells in the same system. Growth factors were assayed using a modification of a double-layer agar technique⁹ or a single-layer technique.¹⁰ McCoy's media was supplemented with 0.8% minimal essential medium (MEM) essential amino acids, 0.4% MEM nonessential amino acids, 2 mmol/L of L-glutamine, 16 μ g/mL of L-asparagine, 8 μ g/mL of L-serine, 1 mmol/L of sodium pyruvate, 1×10^{-4} mol/L of 2-mercaptoethanol, and 15% pretested FCS. Marrow or factor-dependent cell line cells were included at different

concentrations directly in the 0.3% agar-McCoy's layer. The substances to be assayed for growth factor activity were included in different concentrations in the 0.5% agar-McCoy's underlayer in most experiments with the double-layer systems; however, in some experiments using either single-layer or double-layer cultures, the stimulus was included in the 0.3% agar-McCoy's layer. These soft agar cultures (35-mm Petri dishes, Linbro 24-well plates, microtiter plates, or Terasaki dishes) were then incubated at 37 °C, 5% CO₂ for varying time intervals (1 to 22 days), dependent on the particular experimental protocol. IL 3 purified from WEHI-3-conditioned medium¹¹ was obtained from Dr James Ihle and CSF-1 purified from L cell CM¹² was obtained from Dr Richard Shadduck. Murine lung CM, prepared from ICR mice as previously reported,¹³ was used as a source of GM-CSF. Alternatively, CM from Concanavalin A (Con A)-stimulated Balb-C spleen cells was separated by DEAE-cellulose and Sephadex chromatography as described by Ihle and co-workers.¹⁴ Material separated from IL 3 and stimulating GM colony formation was used as a source of partially purified GM-CSF.¹⁴ The morphology of colonies was determined by microscopic analysis of whole agar mount slide preparations stained with either benzidine hematoxylin or acetylcholinesterase-hematoxylin as previously reported.⁸

Colony Criteria

Colonies of >50 cells were counted as granulocyte, macrophage, GM, or mixed megakaryocyte⁸ and colonies that contained three or more acetylcholinesterase-positive cells were scored as megakaryocyte colonies. Routinely, colonies were scored in agar dishes or whole agar mount slide preparations using an Olympus inverted microscope with an ocular micrometer as 0.5 to 1, or >1, 2, or 3 mm in greatest diameter, and as compact or loose. The loose category included all other groupings, some of which had relatively small numbers of cells widely scattered over a 2- to 3-mm diameter.

Mixed colonies were defined as colonies with at least 3 separate areas of the minor cell type or a single area of more than three cells. Almost all mixed colonies had >20 cells of the minor type, and most GM colonies of >1 mm had large numbers of each cell type. Other special colony types are cited in the Results section.

³HtdR Incorporation in Factor-Dependent Cell Lines

The effects of factors on FDC-P1 or DA-1 ³HtdR incorporation were assessed as described by Ihle and colleagues.¹⁴ The cells were washed three times with RPMI 1640 without WEHI-3 CM and resuspended in the same media at 1 × 10⁶ cells/mL. Doubling dilutions of test samples were added to 12 microtiter wells at 50-μL vol; 50 μL of cell suspension was then added to each microtiter well. Plates were then incubated at 37 °C, 5% CO₂ for 24 to 72 hours and pulsed with 1 μCi/well of ³HtdR (specific activity 6.7 Ci/mmol) 5 hours prior to harvest. Cells were harvested on a Skatron harvester; ³HtdR incorporation was then determined by counting on a Beckman Beta-scintillation counter. Results are expressed as cpm.

CSF-1 Studies and Immunoabsorption

CSF-1 levels were determined by radioimmunoassay (RIA), and antiserum to CSF-1 was produced in male New Zealand white rabbits as previously reported.¹⁵ This antiserum was covalently bound to cyanogen bromide-activated Sepharose 4B. TC-1 CM (usually 10× concentrated) was applied to this column after preparatory dialysis against 0.05 mol/L of Tris, 0.15 mol/L of NaCl, and 0.3% polyethylene glycol (PEG) buffers, pH 7.5, to remove CSF-1. The run-through or unbound material was collected, the column was rinsed with 300 mL of buffer, and the CSF-1 was eluted with 25 mL of 2 mol/L of guanidine pH 4.0 in starting buffers. Guanidine was

removed from the purified CSF by repeated diafiltration in an Amicon ultrafiltration cell.

Biochemical Characterization of CSF-1-Dependent Synergistic Activity

Collection starting material. Initial studies were made using TC-1 CM with 5% FCS. With Nutridoma-SF supplement, the FCS concentration was reduced to 1%, and this material was used for some of the more recent studies. Thus far, reduction to no serum results in viable cells that do not produce synergistic activity. Material was pooled, and stored at -20 °C until further manipulation.

Concentration and protein determination. Amicon ultrafiltration units or a spiral cartridge was used with YM 10 (10-kd mol wt cutoff) or YM 100 (100-kd mol wt cutoff) ultrafiltration membranes. No significant loss of bioactivity occurred in the concentrates. Total protein was determined by the Bradford assay.¹⁶

Ammonium sulfate precipitation. Ammonium sulfate precipitations were performed by addition of solid crystal ammonium sulfate (Ultrapur—Schwartz/Mann Biotech, Cambridge, MA). An initial cut of 0% to 35% (0.209 g/mL) was done by slow addition of crystal to a stirred flask of media. The sample was precipitated for 20 minutes at 4 °C. The mixture was centrifuged at 10,000 rpm in an IEC B20A centrifuge in 200-mL vol for 30 minutes at 4 °C. The supernatant was decanted, and a second cut of 35% to 65% (0.198 g/mL) was carried out. The precipitate from the second cut was resuspended in a minimal volume of 0.01 mol/L Tris-HCl pH 7.4, 0.02% Na azide, 0.01% PEG 6000, and dialyzed in the same buffer for 1 to 2 days at 4 °C with three changes per day.

DEAE-Cellulose chromatography. DE-52 resin (Whatman, Clifton, NJ) was prepared, defined in a standard manner, and then equilibrated in 0.01 mol/L of Tris-HCl pH 7.4. TC-1 CM 1× (4 to 5 liters) was added to the resin at a TC-1 CM/resin volume ratio of 4:1 or 5:1, stirred gently, and placed at 4 °C for 2 hours with gentle stirring every 30 minutes. The slurry was poured through a Kimex funnel, and the nonadherent fraction was set aside. The resin was then washed with 0.01 mol/L of Tris HCl pH 7.4 until the wash was free of protein. The adherent proteins were eluted from the resin with 1 mol/L of NaCl in 0.01 mol/L of Tris HCl pH 7.4 or with a linear gradient of 0 to 0.8 mol/L of NaCl. The eluate was concentrated using an Amicon spiral cartridge and 10K membrane to ~100 mL, and this concentrate was dialyzed against 0.01 mol/L of Tris HCl pH 7.4 for 1 to 2 days with three changes per day.

Sephacryl S300 chromatography. A Sephacryl S-300 column (2.5 cm × 49.5 cm, 243-mL bed volume) was equilibrated to 0.5 mol/L of NaCl, 0.02 mol/L of Tris HCl pH 7.4, 0.02% Na azide, and 0.01% PEG-6000. Fractions of 6 mL were collected at 70 mL/h. Samples to be applied were dialyzed in the equilibrating buffer. For bioassays, fractions were pooled in groups of five and concentrated on Amicon 10K membrane threefold.

Sephadex G100 chromatography. Sephadex G100 (Superfine, Pharmacia, Piscataway, NJ) (2.5 × 85 cm/resin 417-mL vol) was equilibrated with 2 L of 0.01 mol/L of Tris-HCl pH 7.4, 0.02% Na azide, and 0.01% PEG 1000; the sample was applied (void vol 1% to 20%) and run at 60 mL/h. Fractions of 15 to 18 mL were collected and pooled (three to five fractions per pool), concentrated (three to five times), and sterile-filtered (0.22 μ) for bioassay.

Con A Sepharose chromatography. Con A Sepharose (Pharmacia) was equilibrated in 0.5 mol/L of NaCl, 0.02 mol/L of Tris-HCl pH 7.4, 0.01% PEG-6000, 0.02% Na azide, and a column (2.5 × 14.5 cm) with a bed volume of 72 mL generally used. Samples of TC-1 applied generally were active fractions that had been sequentially separated by DE-52 and/or Sephadex G-100 or Sephacryl S-300 chromatography. The sample, equilibrated in the

Table 1. Effect of Anti-IL-3 Antibody on TC-1 CM Stimulated Giant Colony (>1 mm) Formation

Group	Giant Colony/10 ⁶ Cells
TC-1-10× (8.3%) + McCoy's 1× (8.3%)	20 ± 3
TC-1-10× (8.3%) + anti-IL 3 IgG (1 mg/mL)	23 ± 2.4
TC-1-10× (8.3%) + control IgG (1 mg/mL)*	29.3 ± 2.4

CM, conditioned media.

In this experiment, anti-IL 3 antibody blocked colony formation by 166 U/mL of IL 3; in other experiments, a level of 1 mg/mL was sufficient to block FDC-P1 proliferation completely.

*IgG purified from normal rabbit sera by protein A chromatography (courtesy of Dr James Ihle).

Con A equilibration buffer was applied, the run-through was collected, the column was washed with 100 to 150 mL of the equilibration buffer, and the column was then eluted with 500 mL of an α -methyl mannoside gradient (0 to 0.25 mol/L). Fractions of 4 to 5 mL were collected at 10 mL/h, pooled (five fractions per pool), concentrated on an Amicon 10K membrane, and dialyzed into phosphate-buffered saline (PBS) pH 7.4 for subsequent bioassay.

RESULTS

Previously, we reported that the murine marrow adherent cell line TC-1 produced CSF-1 and a factor that interacted synergistically with CSF-1 to stimulate giant macrophage colonies. This factor had no intrinsic colony-forming ability, but may still represent relatively low levels of IL 3. Accordingly, we evaluated the capacity of two different antibodies to IL 3 to block giant colony formation induced by TC-1 CM. IL 3 antibodies at a concentration that abolished IL 3 colony formation and FDC-P1 (the IL 3-responsive assay cell line) proliferation did not block giant macrophage colony formation (Table 1). These data suggest that the TC-1 synergistic activity is not IL 3.

Synergism With IL 3

IL 3 has been shown to stimulate granulocyte, macrophage, GM-megakaryocyte and mixed megakaryocyte-GM colony formation. We previously established half-maximal values for IL 3-stimulated hemopoietic colony formation; depending on colony type, these ranged from 0.14 to 0.76 ng/mL.⁶ Plateau levels for all types of colony formation were

Fig 1. Synergistic effect of TC-1 conditioned media (CM) on Interleukin 3 (IL 3) stimulation of post-5-fluorouacil (5-FU) marrow cells. Photomicrograph of whole agar (double-layer) slide preparations stained with acetylcholinesterase and hematoxylin (magnification $\times 1.3$). Murine BDF₁ marrow cells were harvested 3 days after 150 mg 5-FU/kg body weight and 0.5×10^5 cells/mL were cultured in a double-layer agar assay with 1.7 ng/mL of IL 3 (panel A), 8.3% 20 $\times$ TC-1 CM (panel B) or 1.7 ng/mL IL 3 plus 8.3% 20 $\times$ TC-1 CM (panel C). Slide preparations were made after 22 days of culture.

achieved with concentrations of >3 ng/mL and, using these plateau levels of IL 3, we previously showed that crude TC-1 CM (with CSF-1) interacts with IL 3 to induce giant mixed GM and GM-megakaryocyte colonies from normal murine marrow.¹⁷ In this setting, total colony formation is increased only modestly by the combination of TC-1 CM and IL 3, with most of the increase accounted for by GM colonies (Table 2). The major synergistic effect is thus on the size and cell content rather than on the number of colonies. Furthermore, only with the IL 3/TC-1 CM combination were giant compact colonies of granulocytes, macrophages, and megakaryocytes seen. In the present studies, we show a similar potentiating effect of TC-1 CM plus IL 3 on target marrow harvested at 1 and 3 days after 5-FU 150 mg/kg, but peak growth and maximum effect occurred somewhat later than with normal marrow, ranging from 14 to 24 days of growth in soft agar culture (Fig 1). Potentiation of IL 3-induced colony formation by TC-1 CM occurred at from 0.52 to 16.7 ng IL 3/mL and was noted at different TC-1 CM plateau levels (data not shown). Because CSF-1 acts synergistically with IL 3 to give rise to giant macrophage colonies and CSF-1 is present in the crude TC-1 CM, it was important to study the role CSF-1 might play in the observed synergism between TC-1 CM and IL 3. Accordingly, we studied TC-1 CM that had been totally depleted of CSF-1 (as determined by RIA) by affinity CSF-1 antibody column chromatography. Three different pools of TC-1 CM (concentrated ten times) were passed over a Sepharose column to which

Table 2. Colony Formation (>50 Cells) Stimulated by Different Hematopoietic Growth Factors

Colony	Colony/0.5 $\times 10^5$ Marrow Cells				
	TC-1	IL 3	LCM	TC-1 + LCM	TC-1 + IL 3
Macro	109 ± 10	72 ± 9.7	28.7 ± 4.6	33.1 ± 4.7	92.3 ± 11.5
GM	26.1 ± 4.7	26.5 ± 6.8	50 ± 5.6	71.1 ± 5.3	57.7 ± 4.2

Total	151 ± 11.4	139 ± 10.2	106 ± 6.8	126 ± 7.8	180 ± 9.8

IL 3, Interleukin 3; Macro, macrophage; GM, granulocyte-macrophage; Gran, granulocyte; Mega, all megakaryocyte colonies of over 3 cells plus mixed megakaryocyte colonies; total, sum of all colony types.

Data are presented as mean $\pm$ 1 SEM from 8 to 9 individual slide preparations from 3 separate experiments. Stimuli either by themselves or in combination were tested at the following concentrations: TC-1 conditioned media (CM) 8.3% to 15.4%; IL 3 7.7 to 16.7 ng/mL; and LCM 7.7% to 8.3%.

Table 3. Effect of TC-1 "Unbound" Fraction on IL-3-Induced Colony Formation

Group	Mega	Colonies/5 × 10 ⁴ Cells		
		Total Mega	>2 mm	>1 mm
IL 3	7.5 ± 4.3	10 ± 4	3.7 ± 1.2	51 ± 19
IL 3 + unbound fraction	17.3 ± 4.7	24.3 ± 6.2	19 ± 9.3	67 ± 21

These data are from three separate experiments testing TC-1 conditioned media (CM) that had been passed over an anti-CSF-1 Sepharose column (unbound fraction) and was free of CSF-1 activity by radioimmunoassay. In these experiments, both normal murine ICR and BDF₁ target marrow cells were used, and Interleukin 3 (IL 3) levels varied between 43 and 160 U/mL. Unbound activity represented the run-through fraction and thus was equivalent to a 10× TC-1 CM concentrate devoid of CSF-1. Potentiation occurred in different experiments with final unbound concentrations of 1% to 25%. Unbound fractions at higher concentrations ordinarily caused inhibition of growth but this inhibition varied with different pools, and the concentration at which it was seen varied considerably between the different pools.

Mega, pure megakaryocyte colonies of more than three cells; total mega, pure and mixed mega colonies; >2 mm mixed, colonies >2 mm in diameter predominantly granulocyte-macrophage (GM) or macrophage, but also including GM-Mega.

purified anti-CSF-1 was covalently bound. The run-through or unbound fraction had no CSF-1 by RIA and did not stimulate murine marrow colony formation. The CSF-1 eluted off the column with guanidine synergized with the unbound material to give giant colonies, confirming our previous observations.² This unbound material when added at different concentrations to different levels of IL 3 (five separate experiments) potentiated megakaryocyte colony formation and the formation of giant GM and GM-megakaryocyte colonies (Table 3). The actual numbers of different-sized groups fail to convey the true extent of this synergy, as illustrated in two experiments assessing synergy with normal or post-5-FU marrow (Figs 2 and 3). Colonies characteristic of IL 3 plus TC-1 stimulation were very large with a tight central core of cells consisting of granulocytes, macrophages, and megakaryocytes. Furthermore, with post-5-FU marrow colonies of >2 to 3 mm in diameter with central dense cells of >1 mm were seen only in the TC-1 unbound material + IL 3 group (7 ± 1/5 × 10⁴ cells), not in the IL 3 group.

The crude TC-1 CM plus IL 3 tested against post-5-FU marrow over 14 to 22 days of clonal agar culture had variable

Fig 2. Synergistic effect of TC-1 "unbound" fraction on Interleukin 3 (IL 3) stimulated colony formation. Photomicrograph of whole agar slide preparations stained with acetylcholinesterase and hematoxylin. Murine BDF₁ cells (0.5 × 10⁶/mL) were cultured in a single-layer agar assay with 25% unbound fraction (panel A), 25 ng/mL of IL 3 plus 25% unbound fraction (panel B), or 25 ng/mL of IL 3 (panel C). Slide preparations were made after 7 days of culture.

Fig 3. Synergistic effect of TC-1 "unbound" fraction on Interleukin 3 (IL 3) stimulation of post-5-fluorouracil (5-FU) marrow cells. Photomicrograph of whole agar (double-layer) slide preparations stained with acetylcholinesterase and hematoxylin. Murine BDF₁ marrow cells were harvested 3 days after 150 mg of 5-FU/kg body weight and 0.5 × 10⁶ cells were cultured in a double-layer agar assay with 2% unbound fraction (panel A), 2% unbound fraction plus 4.3 ng/mL of IL-3 (panel B), or 4.3 ng/mL of IL 3 (panel C). Slide preparations were made after 22 days of culture.

effects on the numbers of colonies >50 cells. The addition of TC-1 CM to IL 3 resulted in total colony formation that ranged from 56% to 95% of the combined IL 3 and TC-1 CM controls (ie, adding numbers of colonies stimulated by IL 3 alone and TC-1 CM alone). When the "unbound" TC-1 material was added to IL 3 and tested against post-5-FU marrow, total colony (>50 cells) formation was reduced to 74% to 85% of the IL 3 control. Thus, the major effect of the synergistic activity in TC-1 CM when added to IL 3 is to increase colony size with no overall stimulation (and in some cases, apparent inhibition) of total colony formation.

Similar results occurred when plateau concentrations of murine lung CM (a source of GM-CSA-2) were assayed in the presence of plateau concentrations of TC-1 CM; giant mixed GM colonies predominantly of the loose type were seen (Fig 4). Again, within a specific size range and category, colonies from the TC-1 + LCM group had more cells. Total colony formation was modestly depressed by the TC-1 + LCM combination as compared with TC-1 alone, but individual GM colony formation was augmented (Table 2). Again this synergizing effect was seen over varying concentrations of 10× TC-1 CM (0.4% to 11.5%), LCM (0.4% to 11.5%), or 10× LCM (1.19% to 3.8%) and when post-5-FU marrow was used as a target marrow (Fig 5). In the latter case, as with the IL 3 studies, peak growth and potentiation effect with the 5-FU marrow occurred at 14 to 22 days of soft agar culture. The effect of TC-1 CM on LCM-induced colony formation was confirmed in six separate experiments.

Fig 4. Synergistic effect of TC-1 conditioned media (CM) on LCM-stimulated colony formation. Photomicrograph of whole agar (double-layer) slide preparations stained with acetylcholinesterase and hematoxylin (magnification ×1.3). Murine BDF₁ marrow cells (0.5 × 10⁶ cells/mL) were cultured in a double-layer agar assay with 11.5% 10× TC-1 CM (panel A), 3.8% LCM (panel B), or 11.5% 10× TC-1 CM plus 3.8% LCM (panel C). Slide preparations were made after 14 days of culture.

Fig 5. Synergistic effect of TC-1 conditioned media (CM) on LCM stimulation of post-5-fluorouracil (5-FU) marrow cells. Photomicrograph of whole agar (double-layer) slide preparations stained with acetylcholinesterase and hematoxylin (magnification $\times 1.3$). Murine BDF₁ marrow cells harvested 3 days after 150 mg of 5-FU/kg body weight were plated at 0.5×10^6 cells/mL in double-layer agar and cultured for 22 days with 8.3% LCM (panel A), 8.3% 10 $\times$ TC-1 CM (panel B), or 8.3% LCM plus 8.3% 10 $\times$ TC-1 CM (panel C).

We also evaluated unbound fractions free of CSF-1 for their ability to synergize with murine lung-CM, a crude source of GM-CSA, or with a partially purified GM-CSA derived from Con A-activated Balb-c spleen CM (three separate experiments). The potentiation, although less dramatic than that which occurred with unseparated TC-1 CM, was still present (Fig 6) affecting predominantly GM and M colonies. As with unbound material interacting with IL 3, variable high-dose inhibitors were noted.

Characterization of the CSF-1-Dependent Synergistic Activity Present in TC-1 CM

Using giant macrophage colony formation (>0.5 - and >1.0 -mm diameter dense colonies) and carrying out clonal agar cultures with and without added pure CSF-1 (400 to 800 U/mL), we characterized the CSF-1-dependent synergistic activity present in TC-1 CM as nondialyzable (membrane cutoff 3,000), relatively heat stable (56 °C for 30 minutes) with a pH range between 4 and 8. It is stable on storage at 4 °C for at least 6 weeks and is stable to three or four freeze-thaws. During purification, synergistic activity was seen in fractions that also had significant levels of CSF-1, and adding CSF-1 in the assays did not reveal fractions with SA separate from CSF-1. Thus, the data presented represent the capacity of the various separated fractions to stimulate giant colony formation without added CSF-1. The SA was retained on both Amicon PM 10 (10,000 mol-wt cutoff) and Amicon PM 100 (100,000 mol-wt cutoff) and precipitated between 35% and 65% ammonium sulfate. The synergistic activity bound to DE-52 cellulose (What-

Fig 6. Synergistic effect of TC-1 unbound fraction on LCM-stimulated colony formation. Photomicrograph of whole agar slide preparations stained with acetylcholinesterase and hematoxylin. Murine BDF₁ cells (0.5×10^6 /mL) were cultured in a single-layer assay with 12.5% unbound fraction (panel A), 12.5% unbound fraction plus 12.5% LCM (panel B), or 12.5% LCM (panel C). Slide preparations were made after 7 days.

man, Clifton, NJ) that had been equilibrated in 0.02 mol/L of Tris-HCl, pH 7.4 (conditions in which IL 3 does not bind) and eluted from the column between 0.1 and 0.4 to 0.5 mol/L of NaCl (Fig 7). TC-1 CM after ammonium sulfate precipitation or DE-52 cellulose batch elution and separation by Sephadex G100 or Sephacryl S300 chromatography had an apparent mol wt of $>60,000$ ($\sim 200,000$ by Sephadex G100) (Fig 8). The bulk of SA from crude or partially purified TC-1 CM bound to Con A eluting with α -methyl mannoside (Fig 9). A series of sequential separations resulted in significant purification and increase in specific activity (Table 4).

TC-1 CM was separated by DE-52 cellulose chromatography followed by G100 Sephadex chromatography. Active pools from the G100 column were rendered CSF-1-free by passage over an affinity CSF-1 antibody column. This "unbound" material synergized with stage-1 CSF-1 to give tight colonies >0.5 mm in diameter (Fig 10). The same unbound material tested at 13% concentration against normal murine marrow in the presence of IL 3 increased large (>1 mm) colony formation to 169% of the IL 3 control and, at a 5% concentration, caused a 3.14-fold increase in murine pre-B cell generation (as determined by cytoplasmic IgM-positive cells) in a liquid culture system.¹⁸ In addition, when target bone marrow cells from Balb/c mice harvested 8 days after 150 mg of 5-FU/kg were used and these cells were cultured for 14 days at 7% O₂, this same unbound preparation tested at 13% augmented IL 3 stimulation of colonies (>0.5 mm) by 360% of control. Similarly, material that had been subjected to sequential separation over DE-52 cellulose, G100 Sephadex and Con A chromatography (the α -methylmannoside eluate) and that had been rendered free of CSF-1 by CSF-1 antibody affinity chromatography increased pre-B cell generation fivefold.¹⁸

Other Growth-Promoting Activities in TC-1 CM

We recently reported the presence of a murine pre-B cell-inducing activity in crude and partially purified TC-1 CM separate from CSF-1.¹⁸ This activity was found in synergistic activity-active fractions separated by sequential

Fig 7. Separation of TC-1 conditioned media (CM) on DE-52 columns. TC-1 CM (5% fetal calf serum (FCS), concentrated 10 $\times$ Amicon PM10), ammonium sulfate precipitated (35% to 65%), dialyzed, and applied to DE-52 column in 0.02mol/L of Tris-HCl pH 7.4. NaCl gradient (0 to 0.8 mol/L) buffer was applied. Bioactivity is defined as >1 mm macrophage colonies per milliliter with double-layer agar system using normal ICR mouse bone marrow.

Fig 8. Separation of TC-1 conditioned media (CM) by Sephadex G100 chromatography. Two 7-L pools of TC-1 CM (5% fetal calf serum) were separated by batch diethylaminoethanol (DEAE)-cellulose chromatography, and the active salt eluates were then equilibrated with 0.01 mol/L of Tris HCl pH 7.4, 0.02% Na azide, and 0.01% polyethylene glycol (PEG)-6000. Fifty milliliters of this eluate was applied to a Sephadex G 100 (2.5 × 85 cm/resin volume = 417 mL) column that had been equilibrated with 2 L of 0.01 mol/L of Tris HCl pH 7.4, 0.02% Na azide, and 0.01% PEG-6000. Fractions were collected at a rate of 60 mL/h with 16 mL per fraction, and aliquots from three fractions were combined for each pool, concentrated (1.8 to 3 times), and sterile filtered (0.22 U/mL). CSF-1 on the pools was determined by radioimmunoassay (RIA),¹⁶ and protein was determined by Bradford assay.¹⁸ Growth factor results are expressed as the number of tight colonies of >0.5-mm diameter stimulated per milliliter of CM.

DE-52 cellulose, Sephadex G100, Con A, and CSF-1 antibody affinity chromatography. We also noted an activity in TC-1 CM stimulating FDC-P1 (Fig 11) or DA-1 cell proliferation. This material also stimulated FDC-P1 cells that had been selected for TC-1 growth factor sensitivity, although the kinetics of stimulation were altered; moreover, in this case, by 74 hours of growth, there was a higher rate of proliferation of the FDC-P1 TC-1 sensitive cells grown in TC-1 CM as compared to WEHI-3 CM (a source of IL 3) (Fig 11).

DISCUSSION

We present a characterization of a multilineage synergistic activity produced by the murine adherent marrow cell line TC-1. We have shown that a non-IL 3 activity is capable of synergizing with IL 3 to produce giant mixed GM and GM-megakaryocyte colonies and to enhance megakaryocyte colony formation. These data show that CM from the cell line devoid of CSF-1, and with no intrinsic colony-forming ability by itself, contains this synergizing activity for IL 3. This synergy occurs against both normal bone marrow and marrow from animals pretreated with 5-FU (Figs 2 and 3). Similarly, an activity present in the TC-1 CM is capable of synergizing with a source of GM-CSA, ie, murine lung CM, to give rise to giant GM colonies (Figs 4 through 6). This effect, while lessened with the removal of CSF-1, is still present. We previously showed the existence of an activity that synergizes with CSF-1¹²; thus, the TC-1 cell line is

capable of producing a bioactivity that has no intrinsic CSA but that appears to be able to augment the effects of three separate regulators—CSF-1, IL 3, and probably GM-CSA. In these same preparations, we also found an activity capable of inducing pre-B cells in short-term cultures of murine marrow cells.¹⁸ Thus, we found activities from the TC-1 stroma line that appear to act early in both B lymphopoiesis and myelopoiesis.

Pre-B lymphocyte-inducing factor was first found in the urine of patients with cyclical hematopoiesis.^{19,20} In this condition, at a time when myelopoiesis is depressed and just preceding a wave of pre-B cells in the bone marrow, high levels of a pre-B-inducing activity exists in the urine of these patients.²⁰ We may be dealing with a similar type of activity from the adherent cell line described in this article. This cell line was isolated from long-term murine cultures by differential trypsinization using Fischer's media supplemented with FCS and no hydrocortisone. This was initially done to facilitate isolation but we now realize that these conditions may well be permissive for B lymphopoiesis in vitro and approach those described by Whitlock-Witte for long-term B lymphocyte cultures.²¹ In addition, Dorshkind recently showed that the classical myeloid Dexter murine cultures can be switched to cultures supporting B lymphopoiesis by altering the culture conditions. These alterations included using horse serum rather than FCS and omitting hydrocortisone.²² This suggests that one primary stromal cell may be able to provide the environment for supporting both B lymphopoiesis

Fig 9. Separation of TC-1 conditioned media (CM) by Concanavalin A (Con A) Sepharose affinity chromatography. TC-1 CM eluted from batch DE-52 resin was applied to Con A Sepharose column and eluted in 0.1% α -Methylmannoside in 0.5 mol/L of NaCl, 0.02 mol/L of Tris-HCl pH 7.4, 0.02% azide, 0.001% polyethylene glycol (PEG)-6000. HPP/mL defined as >1-mm macrophage colonies in double-layer agar system using normal ICR mouse bone marrow.

and myelopoiesis and that the lineage favored may be dependent on the specific conditions of the cell. It is possible that the myeloid synergizing activity and the pre-B factor seen in the TC-1 supernatants represent the same factor (thus far, they co-purify in biochemical purifications) and that this factor is produced by stromal cells under either condition. The final pathway may be determined by the production of additional factors specific for B lymphopoiesis or myelopoiesis. In support of this hypothesis, the Dexter culture system appears to produce both CSF-1² and GM-CSA,²³ thus providing the terminal differentiating hormones that could account for all the noted phenotypic end cells produced in this system, ie, granulocytes, macrophages, and megakaryocytes. In the CM from the TC-1 line, we recently found an activity similar to that of BCGF-2 which stimulates differentiated B cell proliferation.²⁴ The activity in the TC-1 conditioned media is unique in that IgM secretion is not stimulated. This suggests the presence of a differentiated B cell factor along with an earlier acting B cell factor, possibly providing a model of factor relationships in the Whitlock-

Table 4. Purification of TC-1 Derived LHGF

Sample	Tight Colony/ 5×10^4 Cells/mg Protein		Total Units	
	>0.5 cm	>1 cm	>.5	>1
Original TC-1 CM*	59	31	544,864	289,249

G-100 Sephadex Pool 3	7,996	3,553	366,537	162,870

Abbreviation: LHGF, lymphohemopoietic growth factor.

*Starting pool of 7 L of 5% TC-1. Only 50% of diethylaminoethanol (DEAE)-salt eluate went to G 100 column. G-100 active pools from a similar separative sequence were separated by Concanavalin A chromatography and eluted with α -methyl mannose. Fractions from this separation had synergizing activity but no detectable protein by Bradford assay.¹⁵

Fig 10. Synergistic activity of TC-1 conditioned media (CM) purified by diethylaminoethanol (DEAE) cellulose, Sephadex G-100 chromatography, and CSF-1 antibody affinity chromatography. TC-1 CM was separated by batch DEAE cellulose elution and G-100 Sephadex chromatography. Active fractions from the G-100 column were pooled and passed over an anti-CSF-1 affinity column. This "unbound" material was tested at various concentrations for its capacity to synergize colony formation by stage 1 CSF-1 derived from L cell CM. This latter material represents the eluate from a batch Ca phosphate gel¹⁷ and was included in single-layer agar cultures at 533 U/mL. Marrow cells from BDF-1 mice were plated at 5×10^4 cells/mL. Results are expressed as colonies per 5×10^4 cells $\pm$ 1 SEM from one of two separate lot testings that gave similar results.

Witte B lymphocyte cultures. Further work should clarify these alternatives.

We began a biochemical characterization of the synergizing activity using CSF-1 synergy as an assay. We found that the CSF-1 synergistic activity is nondialyzable and relatively heat stable, precipitates between 35% and 65% ammonium sulfate, and binds to DEAE cellulose under conditions in which IL 3 does not.¹⁴ Furthermore, the synergistic activity concentrates on Amicon PM100 membranes and is found near the void volume with both Sephacryl and Sephadex chromatography indicating a relatively high mol wt or, alternatively, the possibility of aggregate formation. This activity on chromatographic separations shows some polydispersity, and the bulk of the material appears to bind to Con A columns, eluting off with α -methylmannoside, indicating the presence of a glycoprotein although some of the material does not bind. Sequential separations through DE-52 cellulose chromatography and G100 Sephadex chromatography result in a 135-fold purification, and separation of this material or similar material on Con A columns results in

Fig 11. Stimulation of FDC-P1-sensitive and TC-1-sensitive FDC-P1 cells by conditioned media (CM) from the TC-1 cell line. FDC-P1 cells or FDC-P1 cells that had been cloned in soft agar in the presence of TC-1 CM and the clones then subcultured in liquid culture with 25% TC-1 CM (TC-1-sensitive FDC-P1 subclone) were tested for their responsiveness to WEHI-3 CM or to CM from TC-1 cells cultured with 1% fetal calf serum (FCS) and Nutridoma-SP supplement (TC-1 1% FCS) or to a 10 $\times$ concentrate of TC-1 CM originally cultured with 5% FCS. Cells were cultured at 6×10^5 cells/mL (TC-1-sensitive FDC-P1 subclone) or 1×10^6 cells/mL (FDC-P1) in RPMI media with 10% FCS for 27, 50, or 74 hours. Plates were pulsed with ^3H TdR (specific activity 6.7 Ci/mmol) 5 hours prior to harvest, and results expressed as cpm.

fractions with no detectable protein but with significant activity. Thus, the synergistic bioactivity appears to be a relatively large mol wt glycoprotein but, given the history of other hemopoietic glycoprotein hormones, the glycoprotein may well have a much smaller mol wt with further purification. Thus far in preliminary studies, the pre-B activity has been found in active fractions through the Con A separation step. The BCGF-2-like activity has also been found in active fractions but appears to partially separate with various chromatographic steps.

Finally, we also found an activity in the TC-1 CM and in partially purified fractions that stimulates the FDC-P1 and DA-1 factor-dependent cell lines.^{25,26} These data probably extend further the number of activities that can stimulate these factor-dependent lines. Hapel and colleagues²⁶ showed that these lines respond to multiple different activities, but they may provide a worthwhile tool for studies of the nature of the growth action and for a possible assay for its purification.

The TC-1-derived activity is similar to activities described previously^{27,28} in that it synergizes with CSF-1. These activities probably are represented by IL 3 and hemopoietin-1.^{3-5,29} The multilineage synergistic activity described from the TC-1 cell line does not appear to be IL 3, based on its lack of intrinsic colony-forming ability, a failure to be inactivated by an antibody to IL 3, and its behavior on DE-52 cellulose columns. It differs from hemopoietin-1^{4,29} in its apparent mol wt, lack of stimulation of total colony numbers in the presence of IL 3, and binding to Con A columns. The X factor described by Iscove³⁰ using a different system of synergy may well be similar to this activity. Recently, two separate activities predominantly stimulating B cell types were described, and both were termed IL 4.^{31,32} Different assays were used to define these factors but a comparison of both IL 4s to our activity will clearly be appropriate.

Finally, based on the above findings and considerations, we speculate that the long-term myeloid and lymphoid *in vitro* cultures are controlled by a series of growth factors. One unifying multilineage synergizing activity may exist for both B lymphopoiesis and myelopoiesis that determines responsiveness of cells to terminal differentiating hormones. We propose that the pre-B-inducing activity and the myeloid synergizing activities represent this activity. Furthermore, we suggest that in the myeloid Dexter cultures the production of CSF-1 by a particular stromal cell type with a secondary production of GM-CSA by stimulated macrophages determines the final lineages seen in this system; macrophages, granulocytes, and megakaryocytes. Similarly, in the Whitlock and Witte B lymphocyte culture system, we suggest that the production of factors acting on the terminal end of the B cell differentiation pathway modulates the production of B cells. The particular culture conditions used may well determine whether these terminal differentiating hormones are produced, thus providing a possible explanation of the switching from B lymphopoiesis to myelopoiesis in these cultures when conditions are altered.

Value of Monoclonal Anti-CD22 (p135) Antibodies for the Detection of Normal and Neoplastic B Lymphoid Cells

By D.Y. Mason, H. Stein, J. Gerdes, K.A.F. Pulford, E. Ralfkiaer, B. Falini, W.N. Erber, K. Micklem, and K.C. Gatter

Two monoclonal antibodies (To15 and 4KB128) specific for the B cell-associated CD22 antigen (135,000 mol wt) are described. On immunoenzymatic analysis of cryostat tissue sections, these antibodies strongly label both mantle zone and germinal center B lymphoid cells in secondary lymphoid follicles (and also scattered extrafollicular lymphoid cells) but are unreactive with other cell types (with the exception of weak reactivity with some epithelioid histiocytes). These reactions differ from those of monoclonal antibodies B1 and B2 (anti-CD20 and CD21) but are similar to those of the pan-B antibody B4 (anti-CD19). One of the anti-CD22 antibodies (To15) has been tested extensively by immunoenzymatic labeling on >350 neoplastic lymphoid and hematological samples. The CD22 antigen was found in tissue sections in most B cell-derived neoplasms, the major

exceptions being myeloma (all cases negative) and a small proportion of high-grade lymphoma (6% of cases negative). In cell smears, the antigen could be found on neoplastic cells in most B cell lymphoproliferative disorders, including common acute lymphoblastic leukemia (ALL) (90% positive) and B cell chronic lymphocytic leukemia (CLL) (89% positive). We conclude that anti-CD22 antibodies are of value for identification of human B cell lymphoproliferative disorders (especially when used in conjunction with anti-CD19 antibodies). Previous reports that the CD22 antigen is absent from many B cell neoplasms are probably due to its being expressed within the cytoplasm of immature B cells rather than on their surface.

WIDESPREAD use has been made in recent years of monoclonal antibodies for the immunocytochemical identification of lymphoid cell populations in human tissue and blood samples. The first of these reagents to be characterized were directed against T cell antigens, and at the 1st International Workshop on Human Leucocyte Differentiation Antigens (held in Paris in 1982) eight different T cell-associated molecules were defined.¹ Following the convention established at that Workshop, these molecules are prefixed by the letters CD and listed from 1 to 8.

An equivalent number of B cell-associated markers was not defined at the first Workshop, the only categories emerging at that time being CD9 (a 24,000 mol wt molecule shared between B cells and renal tissue) and CD10, the Common-ALL antigen (CALLA). A number of new B cell-associated molecules were, however, defined in the second Workshop (held in Boston in 1984) and numbered CD19 through 24.² Several of these appear to be restricted to B cells, whereas others are shared between B cells and dendritic reticulum cells (the antigen-presenting cell found in B cell follicles).³

Although these B cell-associated molecules are clearly defined entities, little information is available on their relative value as markers in the immunocytochemical detection of human B cell neoplasms. In the present article, we describe our experience in using two monoclonal antibodies against the 135,000 mol wt CD22 antigen for the detection of neoplastic B cells in cryostat sections and cell smears. It is

evident from this study that anti-CD22 antibodies can be confidently used as pan-B reagents for identification of B cell neoplasms, since they react with most such tumors and are unreactive with T cell-derived neoplasms.

MATERIALS AND METHODS

Tissues

Human tissue biopsies were obtained fresh from the Histopathology Department of the University Hospital, Kiel, and from the John Radcliffe Hospital, Oxford, England. Routine tonsillectomy samples were obtained from the Ear, Nose, and Throat Departments of these hospitals. Histological diagnosis was based on examination of paraffin sections stained with hematoxylin and eosin and/or Giemsa, lymphoid neoplasms being classified according to the Kiel system. Immunohistological phenotyping following immunoenzymatic staining of cryostat sections (described later) was performed as described elsewhere.⁴⁻⁶

Cell Samples

Smears of peripheral blood and bone marrow samples from the Hematology Department of the John Radcliffe Hospital and of normal blood from healthy laboratory personnel were stored at -20°C until they were labeled immunoenzymatically. In addition, cytocentrifuge preparations of Triosil-Ficoll-separated mononuclear cells were stored in the same way. Tonsil cell suspensions were prepared and, in some experiments, enriched in follicular dendritic reticulum cells (FDRCs), as described previously.⁷

In some experiments, cytocentrifuge preparations were made from normal peripheral blood mononuclear cells that had been rosetted with neuraminidase-treated sheep RBCs.

Immunocytochemical Reagents

Details of the monoclonal antibodies used in this study and of the immunoenzymatic reagents (eg, PAP, APAAP, peroxidase conjugates) are given in previous publications.^{5,6,8,9} Antibodies B1, B2 and B3 were obtained from Dr L. Nadler and from Coulter.

Immunoenzymatic Labeling Procedures

Tissue sections and cell smears were labeled by a two-stage or three-stage indirect immunoperoxidase procedure,¹⁰ by the PAP immunoperoxidase technique,⁸ or by the APAAP immunalkaline phosphatase technique.^{11,12}

Production of Monoclonal Antibodies to the CD22 B Cell-Associated Antigen

Two antibodies of this specificity were prepared and used in this study.

Antibody To15. A cell fusion experiment was performed using spleen cells from a Balb-c mouse immunized with a potassium iodide extract of normal human tonsil cell membranes.^{13,14} Culture supernatants were screened by immunoperoxidase labeling of tonsil cryostat sections,¹⁵ and one clone (To15) reacting selectively with B cell follicles was cloned and grown by conventional procedures.¹⁴

Antibody 4KB128. Antibody 4KB128 was obtained (by the same hybridoma technique) using spleen cells from a mouse previously immunized with neoplastic cells from a case of hairy cell leukemia.¹⁶

Immunoprecipitation

Immunoprecipitation experiments were performed by conventional procedures, using surface-iodinated human tonsil cells and rabbit anti-mouse Ig bound to Staphylococcal protein A as precipitating reagent. Electrophoresis in sodium dodecyl sulfate (SDS) polyacrylamide gel and autoradiography were performed by conventional techniques.

Purification of Antigen

Membranes extracted from frozen hairy cell leukemia spleen in 2.5% Tween 40 were solubilized in 2% Nonidet P40, 20 mmol/L of Tris-HCl pH 7.5 containing protease inhibitors.¹⁷ The detergent extract was precleared by passage over bovine serum albumin (BSA) coupled to Sepharose 4B, and 25 mL (equivalent to 20 g of original tissue) was then passed down a 5 mL Sepharose 4B:4KB128 antibody column (antibody 4 mg/mL of Sepharose) at 1 mL/h. After being washed with 50 mL of 250 mmol/L of NaCl in 1% Nonidet P40, 20 mmol/L of Tris-HCl pH 7.5 at 2 mL/h, bound antigen was eluted with a 40-mL pH 7.5 linear gradient at 2 mL/h. Fractions were precipitated with 10% trichloroacetic acid (TCA), washed with acetone, solubilized in SDS-urea, and analyzed by SDS polyacrylamide gel electrophoresis (PAGE) using a 7.5% gel and Coomassie blue staining.

RESULTS

Production of Monoclonal Antibodies To15 and 4KB128

Supernatant from two hybridoma cell cultures, To15 and 4KB128, reacted selectively with B cell follicles in lymphoid tissue, and the same pattern was maintained during cloning and subsequent growth of these cell lines.

Mol Wt of Antigen Detected by Antibodies To15 and 4KB128

Antibodies To15 and 4KB128 both precipitated a polypeptide chain with a mol wt under reducing conditions of 125,000 to 135,000. In some experiments, this material appeared as a doublet of two bands of only slightly different mol wts. It was also possible to isolate the CD22 antigen from human tissue using Sepharose antibody immunoabsorbents (Fig 1). This material migrated with the same mol wt as that of the radiolabeled band detected by immunoprecipitation.

Immunocytochemical Labeling of Peripheral Blood Cells

Immunoenzymatic staining of cell smears. Antibody To15 labeled 15% of lymphoid cells (range 10% to 25%) in

Fig 1. Demonstration of the specificity of antibody 4KB128 for the CD22 antigen by elution from an immunoabsorbent column (described in text). In track A, the prominent protein band (arrow) of ~125,000 mol wt represents the CD22 antigen. Small amounts of contaminating protein of lower mol wt are near the bottom of the gel. Track B shows the mol wt (in kD) of marker proteins run on the same gel. The mol wt of the CD22 antigen in this experiment was lower than the conventionally quoted figure (135,000) but in keeping with results reported by other authors²⁴ (Coomassie blue staining).

blood smears from 15 normal subjects. Antibody 4KB128 (tested on a smaller number of samples) labeled essentially the same number of lymphoid cells. Granulocytes, monocytes, RBCs, and platelets were unstained. In cytocentrifuge preparations of peripheral mononuclear cells rosetted with sheep erythrocytes, antibodies To15 and 4KB128 reacted selectively with nonrosetting lymphocytes.

Immunohistological Labeling of Human Tissue Sections

Normal tissue. The two anti-CD22 antibodies labeled B cell follicles with moderate to strong intensity (depending on the labeling procedure used) staining both mantle zone lymphocytes and germinal center cells. In centrifuged preparations of tonsil-cell suspensions enriched for FDRCs, antibody To15 labeled these cells weakly, although this could not

be discerned (because of lymphoid cell reactivity) in tissue sections.

The two anti-CD22 antibodies were compared with the pan-B reagents B1, B2, and B4 (anti-CD20, 21, and 19, respectively). Neither B1 nor B2 labeled B cell follicles as extensively as, or gave reactions of comparable intensity to, the two anti-CD22 reagents. Both B1 and B2 stained follicle mantle zone lymphocytes more weakly than germinal centers, and much of the germinal center staining was in a meshwork pattern in germinal centers characteristic of FDCs (particularly marked with antibody B2). In contrast, antibody B4 was closely similar in its staining reactions to the anti-CD22 reagents, labeling both mantle zones and germinal centers.

In addition to B cell follicles, antibodies To15 and 4KB128 stained scattered small cells in interfollicular and paracortical regions. The two antibodies were unreactive with all nonlymphoid tissue and organs tested (skin, lung, stomach, small and large intestine, kidney, liver, salivary and thyroid gland, urinary bladder, testis, and central and peripheral nervous tissue), with the exception of weak staining of epithelioid histiocytes in granulomatous lesions. Antibody B1 also reacted with epithelioid histiocytes, usually more intensely than the anti-CD22 reagents.

Neoplastic tissues. One of the two anti-CD22 antibodies (To15) was tested against a wide range of neoplasms (Table 1). It labeled most human B cell neoplasms, the principal exceptions being myeloma (consistently negative) and a few high-grade B cell lymphomas (4 negatives in 64 cases). The strength of labeling was usually of moderate intensity and could be enhanced markedly by use of the three-stage immunoperoxidase technique¹⁰ or the "enhanced" APAAP procedure.⁹ The strongest reactions were seen in hairy cell leukemia and B cell prolymphocytic leukemia. The intensity of labeling of cases of common acute lymphoblastic leukemia (common ALL) and B cell chronic lymphocytic leukemia (CLL) varied widely; a number of positive cases showed only weak labeling. Nevertheless, most cases in each of these two disorders gave unequivocally positive reactions.

Other neoplasms analyzed with antibody To15 (Table 1), were unreactive (including 56 cases of T cell lymphoproliferative disease) with the exception of a minority of cases of acute myeloid leukemia. These reactions were usually weak; in one case of acute monocytic leukemia, however, the neoplastic cells were relatively strongly labeled. The other anti-CD22 antibody (4KB128) was tested on a smaller number of neoplasms and gave reactions closely similar to those of antibody To15.

DISCUSSION

Both of the antibodies used in this study appear to recognize the B cell-associated molecule designated CD22. This is evidenced both by the results of immunoprecipitation and affinity chromatography experiments from this laboratory and by similar experiments and statistical analysis of FACS data in the 3rd International Workshop on Human Leucocyte Differentiation Antigens.¹⁸ The observation that in some experiments two polypeptide chains of similar mol wt

Staining was performed on cryostat tissue sections as described in the text, or by the APAAP immunoenzymatic procedure on blood or bone marrow smears, or on cytocentrifuge preparations. In all cases scored as positive, the majority (>70%) of neoplastic cells gave a positive reaction.

*Centroblastic-centrocytic lymphoma is approximately equivalent to follicular lymphoma in other classifications.

†Centroblastic and immunoblastic lymphoma are equivalent to "histiocytic lymphoma, diffuse" in the Rappaport classification.

were immunoprecipitated is in keeping with a similar report from Moldenhauer and colleagues on two other anti-CD22 antibodies.¹⁹

The two anti-CD22 antibodies clearly delineated B cell follicles in cryostat sections of lymphoid tissue and did so with greater clarity than did either B1 (anti-CD20) or B2 (anti-CD21). Hofman and co-workers²⁰ also found that antibody B1 labeled germinal center cells but only a proportion of mantle zone lymphocytes; in contrast, Bhan and co-workers²¹ reported labeling of all cells in lymphoid folli-

cles (both mantle zones and germinal centers). This discrepancy may relate to the relative sensitivities of labeling methods. When adjacent lymphoid tissue sections were stained with antibody B1 and anti-CD22 antibodies, however, the former reagent consistently gave weaker reactions. In this context, the initial detection of the two anti-CD22 antibodies by screening on tissue sections (rather than by binding to cell suspensions, used in screening for antibody B1) may account for their better reactivity as immunohistological reagents.

Anti-CD22 antibodies thus appear to be valuable reagents for labeling B cells in tissue sections and also in cell smears, and are comparable in our experience to antibodies against the 95,000 mol wt B cell-associated marker CD19 (first detected by antibody B4).²² They appear to be specific for B cells, with the exceptions of weak reactions with FDRCs and epithelioid histiocytes. Furthermore, the reaction of anti-CD22 with epithelioid histiocytes and FDRCs was less pronounced than the labeling of these cells by antibodies B1 and B2, respectively.

As shown in Table 1, positive labeling with the anti-CD22 antibodies was obtained in most B cell neoplasms in tissue sections or cell smears. The negative reactions of cases of myeloma is in keeping with observations that a number of other human B cell antigens are lost during terminal differentiation to plasma cells.² The only positive reactions against neoplastic cells other than B cells were those occasionally observed with cells from myeloid leukemia (Table 1). This may be related to the observation that CD22 is weakly

expressed by epithelioid histiocytes (ie, by another cell type of myeloid/monocytic origin).

The broad spectrum of reactivity of anti-CD22 antibodies against neoplastic B cells observed in the present study contrasts with other reports that the CD22 antigen is undetectable on many B cell neoplasms.² This discrepancy may be related to reports that the CD22 antigen is initially found during B cell maturation in the cell cytoplasm, and only subsequently emerges onto the cell surface.^{19,23} In consequence, blast cells in cases of common ALL contain cytoplasmic CD22 but lack this antigen on their surface.^{19,23} Phorbol ester stimulation of common ALL and pre-B cell lines can induce membrane expression of CD22, however.²³ The practical implication of these observations is that immunocytochemical staining methods that allow antibodies to gain access to the cell interior (ie, in fixed cell smears or tissue sections) will reveal cytoplasmic CD22, whereas staining of cells in suspension will only reveal surface membrane antigen.

Whatever the explanation of the higher positivity rate for CD22 antigen on neoplastic B cells in the present study as compared with previous reports,² it is evident that these monoclonal anti-CD22 antibodies will detect most B cell neoplasms studied in tissue sections or cell smears. Because identification of neoplastic cell lineage on the basis of at least two independent markers is advisable, we believe that in routine diagnostic practice a combination of anti-CD19 and CD22 antibodies constitutes a reliable pair of reagents for detecting B cell neoplasms.

Evaluation of Circulating Malignant Cells Provides Prognostic Information in Cutaneous T Cell Lymphoma

By Geraldine P. Schechter, Edward A. Sausville, A. Betty Fischmann, Frances Soehnlen, Joyce Eddy, Mary Matthews, Adi Gazdar, John Guccion, Dianne Munson, Robert Makuch, and Paul A. Bunn, Jr

Peripheral blood lymphocyte morphology was evaluated prospectively by light microscopy of blood smears and E rosette preparations in 160 patients with cutaneous T cell lymphoma (CTCL). Blood involvement was related to the type of cutaneous T-stage, being present in 90% of patients with erythroderma (T4), 27% of those with cutaneous tumors (T3), 9% of those with generalized (T2), and 0% of those with limited skin plaques (T1). Untreated patients with blood involvement (38 of 105) had a higher frequency of CTCL in lymph nodes and viscera and survival inferior to that of patients with normal or nondiagnostic lymphocyte morphology ($P < .001$). Multivariate analysis showed skin stage and age to be the most important pretreatment risk factors for survival. Although blood involvement was not an independent risk factor for the

entire group, it appeared to have some adverse influence in the T2/T3 subsets ($P = .051$). Both lymphocytosis and size distribution of the circulating CTCL cells at initial diagnosis influenced survival. Patients with "mixed cell" cytology ($>20\%$ large [$>11 \mu\text{m}$] CTCL cells), had a worse survival than those with predominantly small circulating CTCL cells ($P = .009$). The former were more likely to have aggressive features, including lymph node effacement by tumor ($P < .001$) and visceral disease ($P = .074$), than were "small cell" patients. Our data indicate that detailed review of the blood lymphocyte morphology in patients with diagnosed or suspected CTCL is helpful in predicting extent of disease and prognosis.

© 1987 by Grune & Stratton, Inc.

FOR MANY YEARS, mycosis fungoides (MF) was considered primarily a cutaneous disorder, with plaques, cutaneous tumors, and erythroderma recognized as types of skin involvement.¹ In 1938, Sézary and Bouvraïn described a group of patients with generalized erythroderma who had large, bizarre mononuclear cells in the peripheral blood.² Similarities between the erythrodermic form of MF and the Sézary syndrome (SS) were soon recognized. In 1970, Crossen and colleagues showed that the abnormal cells of SS were malignant lymphocytes³; subsequently, both MF and SS were shown to be malignant proliferations of mature helper T cells.⁴⁻⁷ Because of their similar clinical and histopathologic features, the term cutaneous T cell lymphoma (CTCL) has been used to include both MF and SS^{8,9} in a spectrum of disease. At one end of the spectrum is non-erythrodermic MF limited to the skin; at the other extreme is SS with erythroderma and frank leukemia.

Using light microscopy, Clendenning and colleagues reported that up to 20% of advanced plaque/tumor MF patients without erythroderma had circulating convoluted cells similar to those of SS.¹⁰ Other investigators reported that these cells could be identified by cytologic features and electron microscopy as well as by cytogenetic and DNA content analyses.¹¹⁻¹⁵

Several studies addressed the clinical implications of blood involvement¹⁶⁻¹⁹; however, systematic evaluation prior to therapy was not fully explored until recently. Vonderheid and colleagues showed that prognosis was influenced adversely when there were $>10\%$ Sézary cells¹⁷ or increased proportions of large convoluted cells.¹⁹ We previously reported that peripheral blood involvement had significant impact on prognosis in a small group of prospectively staged patients.^{20,21} That series has now been extended to 160 patients with CTCL to define the frequency, extent, and morphological variety of circulating CTCL cells detected by light microscopy and to determine the importance of these features for prognosis.

METHODS AND MATERIALS

Patients. The clinical features of the 160 CTCL patients studied by the NCI-Navy Medical Oncology Branch and the Hematology,

Dermatology, or Medical Oncology Sections of the Washington Veterans Administration Medical Center between June 1975 and March 1984 are shown in Table 1. Informed consent for the staging procedures and subsequent treatment was obtained for all patients according to the policies of the human studies review boards of the National Naval Medical Center or the Veterans Administration Medical Center and the National Institutes of Health. Group I comprised 105 patients who were staged within 12 months (median 1.4 months) of initial diagnosis and had received no systemic chemotherapy prior to staging. The remaining 55 patients (group II) had received prior chemotherapy or were staged >1 year from diagnosis and were not evaluated for survival. Group I patients were entered into two sequential CTCL treatment protocols. The first 39 patients were treated with total-skin electron-beam radiotherapy and chemotherapy²²; the remaining patients were randomized to either intensive combined modality therapy or sequential palliative therapies.²³ Group I patients were followed for a median of 54 months.

Staging evaluation. One dermatologist (A.B.F.) characterized the skin lesions using the TNM classification for cutaneous T cell lymphoma.²⁴ In the first 40 patients, a lymph node was biopsied only if lymphadenopathy existed. Subsequently, blind biopsies were also attempted in patients without palpable nodes. The histopathologic

Table 1. Clinical Features of CTCL Subjects

Characteristic	Group I*	Group II†	Total
No. of subjects	105	55	160
M/F	73/32	30/25	103/57
White/black	73/31	44/11	117/42
Age at diagnosis (yr), mean (range)	53 (22–75)	50 (19–75)	52 (19–75)
Time from diagnosis to staging (mo), median (range)	1.4 (<1–12)	34 (<1–176)	2.8 (<1–176)
Skin class n (%)			
T1, limited plaque	13 (12)	4 (7)	17 (11)
T2, generalized plaque	35 (33)	22 (40)	57 (36)
T3, skin tumors	22 (21)	13 (24)	35 (22)
T4, erythroderma	35 (33)	16 (29)	51 (32)

CTCL, cutaneous T cell lymphoma.

*Group I patients were staged within 12 months of diagnosis and had received no systemic cytotoxic chemotherapy prior to evaluation of lymphocyte morphology.

†Group II patients had received prior systemic chemotherapy and/or had been diagnosed > 12 months before evaluation or were lost to follow-up after initial studies.

findings of the lymph node biopsies were classified according to the number of atypical cells in paracortical node areas and the degree of node effacement.²⁵ This classification describes node involvement as LN1 (no atypical cells), LN2 (small clusters of atypical cells), LN3 (large clusters of atypical cells), and LN4 (partial or total effacement of normal architecture by malignant cells). The initial staging evaluation also included a chest x-ray, lymphangiogram, liver biopsy, and bone marrow biopsy. In the last 60 patients, liver biopsy was performed only if adenopathy, LN3 or LN4 node histopathology, or blood involvement existed.

Peripheral blood studies. Peripheral blood lymphocyte morphology was evaluated by one hematologist (G.P.S.) using light microscopy at $\times 1,500$ magnification without knowledge of the type of skin lesions or other physical findings. Every patient had a WBC count and a differential count of a Wright's-Giemsa-stained smear that included evaluation of the nuclear morphology of at least 50 lymphocytes in areas devoid of rouleaux formation. In 145 patients, blood mononuclear cells were isolated by Ficoll-Hypaque centrifugation and the percentage of cells binding AET-treated sheep red cells (SRBCs) (133 patients) or unmodified SRBC (12 patients) was determined.^{26,27} The morphology of 200 E rosetted T lymphocytes was then examined on Wright's-Giemsa-stained cytocentrifuge preparations. Fluorescent antiimmunoglobulin antisera (Meloy, Springfield, VA) and fluorescence microscopy were used to determine the percentage of B cells in 90 patients.

The criteria for the diagnosis of CTCL infiltration of the blood were developed during our initial comparisons of lymphocyte morphology of CTCL patients with that of normal individuals and patients with nonmalignant skin disorders or lymphopenia.²⁰ Atypical cells were grouped in the following categories, except for lymphoid cells with cytoplasmic granules which were excluded. Category 1 describes small convoluted lymphocytes, cells $\leq 11 \mu\text{m}$ in diameter, with a nuclear density similar to or greater than that of normal lymphocytes and having nuclear grooves, cleaves, convolutions, or folds (Fig 1a through c). Category 2 describes large convoluted lymphocytes, cells $> 11 \mu\text{m}$ in diameter with nuclear abnormalities as described in category 1 or with dense hyperchromatic nuclear chromatin (Fig 2a,b). Category 3 describes "atypical" nonconvoluted lymphocytes, cells $> 11 \mu\text{m}$ without nuclear irregularities or convolutions but containing fine nuclear chromatin and/or nucleoli (blastlike or "transformed" cells, Fig 2d, arrow).

A diagnosis of blood involvement by CTCL was made if the sum of the convoluted cells (categories 1 and 2) was $\geq 20\%$ of the

lymphocytes in a blood smear and/or $\geq 10\%$ of the lymphocytes in the E-rosetted cytocentrifuge preparations (ERCs). Category 3 cells were generally not considered diagnostic, except in one patient with marginal numbers of convoluted cells and numerous nonconvoluted tumor cells.

Thirteen blood smears and 15 ERC preparations from 21 patients with $< 4,000$ lymphocytes/ μL , had cells that resembled the small convoluted cell type (category 1) but convolutions were minimal (single folds or small clefts), and category 2 cells were rare or absent. These patients were considered to have abnormal but nondiagnostic lymphocyte morphology. Thus, three groups of patients were identified with respect to their lymphocyte morphology: (a) positive for CTCL, (b) abnormal but nondiagnostic for CTCL, and (c) within normal limits. For purposes of analysis, patients with positive peripheral lymphocyte morphology were in all cases compared with the combined negative and abnormal but nondiagnostic patients.

Fig 1. Peripheral blood lymphocytes in smears and E rosette preparations from three patients with cutaneous T cell lymphoma (CTCL) of the small cell type, original magnification $\times 1,400$; current magnification $\times 910$: (A) mycosis fungoides (T2); (B,C) erythrodermic CTCL (T4). The morphology of the CTCL cells tended to be uniform, with the diameter of $> 90\%$ of the cells between 8.0 and $10.5 \mu\text{m}$.

Fig 2. Peripheral blood lymphocytes on smear and E rosette preparations from five patients with cutaneous T cell lymphoma (CTCL) of the mixed cell type, original magnification $\times 1,400$; current magnification $\times 910$: (A) mycosis fungoides (T3); (B–E) erythrodermic CTCL (T4). The CTCL cells were highly pleomorphic and varied between patients and within the same patient. The diameters ranged between 8 and 17 μm in diameter. Tumor cells containing densely hyperchromatic nuclei (A,B), hyperconvoluted nuclei (B,E,F), nuclei with finely dispersed chromatin without convolutions (D, arrow) or only with vague grooving and rarely with nuclear segmentation were noted.

In patients with positive blood, two groups were identified on the basis of the size distribution of the convoluted cells, a mixed-cell variant and a small-cell variant. Mixed-cell patients had a ratio of category 1 to category 2 cells of <4 , with the percentage of large convoluted cells varying between 22% and 67% of all convoluted cells. In the small-cell patients, the ratio was >4 , and the median percentage of small convoluted cells was 94%. Tumor cells in the small-cell patients were fairly uniform, with round nuclei and subtle to distinct nuclear grooves, simple folding, or figure 8 shapes (Fig 1). Cells $>12 \mu\text{m}$ were rare. Mixed-cell patients demonstrated greater variability in cytologic characteristics. Frequently, a wide range of cell diameters from 8 to 17 μm existed in the individual patient, with a few patients having predominantly large ($>11 \mu\text{m}$) cells. Nuclei were often ovoid, with highly bizarre and pleomorphic convolutions and dense chromatin (Fig 2). In some mixed-cell patients, the tumor cells had more finely divided nuclear chromatin and prominent nucleoli (Fig 2d). Cytoplasm was usually scant in the small-cell patients and frequently abundant in the mixed-cell patients. Occasionally, extensive vacuolation occurred in both variants.

The light microscopic findings were compared with those made independently by J.G. using electron microscopy in 78 consecutive patients. The concordance between the light-microscopic and electron-microscopic interpretations was 84%. In 2 of 33 instances, a positive light-microscopic interpretation was not confirmed by electron microscopy; one of these cases was an erythrodermic patient with a frank leukemia of mature T cells with minor nuclear folding. Eleven patients positive by electron-microscopic criteria ($>6\%$ convoluted cells) were negative (5 patients) or abnormal/nondiagnostic (6 patients) by light microscopy. For the clinical analyses here, these 11 patients were retained in the negative or nondiagnostic groups. The electron-microscopic evaluation of the first 49 patients has been published.²⁸

Control subjects. During this study, the lymphocyte morphology of 71 individuals with diagnoses other than CTCL were also evaluated. This group included 28 normal subjects, 25 subjects with acute and chronic skin disorders, 13 patients with B cell lymphopro-

liferative disorders, and 6 patients with lymphopenia. More than 50% of the preparations from the control subjects were evaluated without knowledge of the diagnosis, interspersed among groups of slides from CTCL patients.

Statistical methods. Comparative analysis of discrete data was performed using standard chi-square tests, corrected for continuity where appropriate. Comparisons between groups of continuous data were made using the nonparametric Kruskal-Wallis one-way analysis of variance.²⁹ Survival curves were estimated from the date of diagnosis to the most recent follow-up date/death date using the Kaplan-Meier method.³⁰ Patients dying from any cause were considered failures, ie, uncensored observations. The method described by Mantel³¹ was used to compare survival curves unadjusted for any covariates. Once these univariate analyses were completed, a multivariate analysis was undertaken to determine the relative importance of several factors, simultaneously using the life-table regression approach of Cox.³² A ranking of the relative importance of these factors was established using both a forward step-up approach and a backward step-down approach. All *P* values in this report correspond to two-sided significance tests. Both approaches gave the same final set of independent and important prognostic factors.

RESULTS

Concordance of the peripheral smear and ERC evaluation in CTCL. Sixty patients (38%) were identified as having one or both preparations (blood smear or ERC) diagnostic for CTCL blood involvement. The remaining patients had either normal lymphocyte morphology (79 patients, 48%) or abnormal/nondiagnostic morphology on either the smear or ERC (21 patients, 14%). Of 145 patients studied, 45 had both positive smear and ERC preparations. The percentage of convoluted cells on smear (Fig 3) correlated significantly with the percentage of convoluted T cells noted on the ERC preparations ($P < .001$). In five patients, one of the preparations was considered positive (ERC 4,

Fig 3. Percentage of convoluted lymphoid cells per 100 lymphocytes in peripheral blood smears in 60 subjects with noncutaneous T cell lymphoma (non-CTCL) and 160 CTCL subjects grouped according to skin stages T1 through T4 and palpable adenopathy in T2. The percentage of convoluted E rosetted cells in the 145 CTCL patients who also had E rosette preparations (data not shown) correlated significantly with the percentage of convoluted cells on smear ($P < .001$).

smear 1) whereas the other was not. Two patients with positive smears had inadequate ERC preparations due to extremely low percentages of T cells ($\leq 12\%$), and eight did not have an ERC study.

An abnormally low percentage of T cells ($< 58\%$ AET- or $< 45\%$ unmodified E rosettes) occurred in 11% of the patients and was associated with blood involvement in 13 of 17 instances. Eleven patients had a low percentage of B cells ($< 4\%$); B cell lymphopenia was apparently due to dilution in six patients with frank CTCL cell leukemia. It was unexplained in five patients with normal lymphocyte counts, three of whom had peripheral blood involvement.

No preparation from the 71 non-CTCL subjects, including 60 blood smears and 24 ERC preparations, met the criteria for infiltration by CTCL cells. Sixty-six non-CTCL subjects had completely normal lymphocyte morphology. Five non-CTCL subjects (7%) had abnormal lymphocyte morphology (smear 4, ERC 2) associated with diagnoses of follicular lymphoma, reaction to phenytoin, severe lymphopenia, and lymphomatoid granulomatosis (Fig 3).

Correlation of circulating CTCL cells with skin, node, and visceral disease. Diagnostic blood involvement was significantly associated with advanced skin disease (Table 2 and Fig 3), with a similar trend for patients with abnormal but not diagnostic morphology. Overall, 90% of erythrodermic (T4) and 13% of the nonerythrodermic (T1 through T3) patients had positive smears and/or ERC preparations. The erythrodermic patients with normal (three patients) or abnormal but not diagnostic (two patients) morphology were all moderately to severely lymphopenic (540 to $1,200/\mu\text{L}$). In patients without erythroderma, blood involvement was always associated with advanced disease, as judged by the presence of adenopathy (if T2) or cutaneous tumors (T3).

No patient with limited plaque disease or generalized plaque without palpable adenopathy had circulating CTCL cells detected by light microscopy. There was no difference in the frequency of blood involvement between group I (no prior treatment) and group II (prior treatment or delayed staging).

The association of blood involvement at initial diagnosis of CTCL (group I patients only) with lymphadenopathy, lymph node histology, and visceral involvement is shown in Table 3. Patients with blood involvement were more likely to have adenopathy ($P = .002$), lymph node involvement (LN3 or LN4) ($P < .001$), and visceral disease ($P < .001$) than were patients with normal or nondiagnostic lymphocyte morphology. Visceral involvement and lymph node effacement (LN4)

Table 2. Correlation of Skin Stage With Circulating CTCL Cells

Patients	No. With Circulating CTCL Cells (%)		
	Group I*	Group II*	Total
T1†	0/13 (0)	0/4 (0)	0/17 (0)

†Liver or marrow biopsy positive.

were uncommon in patients with negative blood findings (5 of 65 and 1 of 57, respectively).

Correlation of lymphocyte number and morphology with other prognostic features in patients with positive peripheral blood. The correlation of lymphocyte concentration, proportion of convoluted cells, and cell size distribution with skin class for all patients (groups I and II) with positive peripheral blood is shown in Table 4. Erythrodermic patients (T4) were significantly ($P = .043$) more likely to have high lymphocyte counts than were plaque/tumor (T2/T3) patients and a higher proportion (>20%) of large cells

Table 4. Lymphocyte Concentration and Cell Morphology Related to Skin Class in Patients With Circulating CTCL Cells

Factor	Skin Class		P
	T2,3 (n = 14)	T4 (n = 46)

‡Mann-Whitney test.

(mixed-cell type) ($P = .043$). T4 patients also had higher proportions of convoluted cells noted on smear than did the T2/T3 patients ($P = .025$).

The correspondence between lymphocyte count or cell size and lymph node biopsy findings and visceral disease in group I patients is shown in Table 5. Patients with small CTCL cells were unlikely to have node effacement at initial diagnosis of CTCL, whereas 83% of patients with mixed-cell type had lymph node effacement (LN4). Visceral involvement at diagnosis was more closely associated with high lymphocyte counts (>4,000/ μL) and, to a lesser extent, with the mixed-cell type ($P = .015$ and $P = .074$, respectively). Lymph node effacement (LN4) was also associated with higher lymphocyte counts but more particularly with the mixed-cell type ($P = .069$ and $P < .001$, respectively). In group I patients, neither type of skin disease nor adenopathy was associated with absolute lymphocyte counts or with cell size.

Mixed-cell patients had a higher frequency of lymphocytosis than did small-cell patients (12 of 20 v 4 of 18, $P = .061$). They also had higher percentages of convoluted lymphocytes and nonconvoluted tumor cells on smear ($P = .008$ and $P = .003$, respectively) and a lower fraction of lymphocytes with normal morphology (in patients with <6,000/ μL , $P = .046$) (Table 6).

Prognostic significance of peripheral blood findings. The actuarial survival of group I patients with diagnostic blood findings is shown in Fig 4. Patients with positive blood, either by smear or cytology, had a survival inferior to that of patients without positive blood ($P < .001$), with estimated 5-year survivals of 22% and 76%, respectively.

Lymphocyte size influenced survival in the patients with positive lymphocyte morphology. The actuarial survival of the mixed-cell patients was significantly shorter than that of patients with the small-cell type (23 v 51 months, $P = .009$;

Fig 5A). Similarly, Fig 5B shows that patients with small-cell CTCL involvement of blood and <4,000 lymphocytes/ μ L had a significantly improved survival in comparison with mixed-cell patients with <4,000/ μ L ($P = .025$) or all patients with abnormal cells >4,000/ μ L ($P = .032$).

Multivariate analysis of prognostic factors. To examine the effect on survival of several parameters simultaneously, the Cox life-table regression method was used in conjunction with two distinct ways of determining what variables would form the final statistical model. For the first approach, all variables given in Table 7 and examined in a univariate analysis were included. Using standard likelihood ratio procedures, a backward step-down approach was used to eliminate those variables found not to be significantly associated with survival at the .05 significance level.

Age, skin class, lymph node histology, adenopathy, and visceral disease as well as blood involvement were each significant predictors of inferior survival when analyzed in a

univariate fashion (Table 7). In the multivariate analysis, the only significant factors were skin class and age ($P < .001$ and $P = .025$, respectively). A forward step-up procedure was used as the second approach and resulted in the selection of these same two factors. With these two variables in the model, all remaining variables were not significant at the $P = .05$ level. Thus, T-class and age remained the most important and independent prognostic indicators of survival, with T1 and T2 patients and those patients aged <50 years associated with a favorable prognosis. Adjusted Mantel-Haenszel analyses also were used to confirm these findings.

Blood involvement was not a significant factor in the final model once age and T-class were included ($P = .31$). This finding is readily explained by the fact that blood involvement and T-class are highly associated ($P < .001$). The importance of age in this model remains although almost all deaths in this series were relatable to progressive cutaneous T cell lymphoma. Further analyses were made to determine if first including blood involvement in the model would eliminate the need for subsequently introducing T-class or age into the model. Because both T-class and age still entered the model, however, blood involvement appears not to have been an independent prognostic factor for the entire group of patients. In the subset of patients with T2 (generalized plaque) and T3 (cutaneous tumor) skin disease, however, blood involvement was ($P = .051$) associated with inferior prognosis (Fig 6). Although the number of patients in the nonerythrodermic, blood-positive subgroup was small, their inferior survival reinforces the potential usefulness of blood involvement in the prospective evaluation of this subgroup of patients with CTCL.

DISCUSSION

In this study of a large number of patients with cutaneous T cell lymphoma, we found that peripheral blood infiltration correlated with established prognostic factors, including advanced skin disease, palpable adenopathy, lymph node and visceral involvement, and older age. In this series, no patient with limited plaque disease or generalized plaques without

Fig 4. Actuarial survival of group I cutaneous T cell lymphoma (CTCL) patients with normal or nondiagnostic peripheral blood morphology (blood negative) differed significantly from that of patients with circulating CTCL cells (blood positive); ($P < .001$).

Fig 5. (A) Actuarial survival of group I cutaneous T cell lymphoma (CTCL) patients with blood involvement of the small cell type differed significantly from that of patients demonstrating >20% large cells (mixed cell type), ($P = .009$). (B) Actuarial survival of small cell type and mixed cell type patients according to lymphocyte concentration. Survival of patients with small cell CTCL with <4,000 lymphocytes/ μL differed from that of patients with mixed cell type with <4,000/ μL ($P = .015$) and from all patients with >4,000/ μL ($P = .032$).

adenopathy had blood involvement. Approximately 22% of plaque patients with adenopathy and/or skin tumors had blood involvement on detailed review of the peripheral blood smear or T cell cytology. In contrast, 90% of those with erythroderma had blood infiltration. In patients with blood involvement, we further identified >20% large convoluted cells or an absolute lymphocytosis as poor prognostic features.

The original description of SS directed attention to the importance of peripheral blood involvement in this disorder.² Many years later, using electron microscopy, Lutzner and co-workers recognized considerable variation in the size of Sézary cells and described a variant in which small cells predominated.¹¹ The recognition that mycosis fungoides and the Sézary syndrome were related disorders, malignancies of mature helper T cells, led to the discovery of circulating

Fig 6. Actuarial survival of plaque and tumor (T2 and T3) cutaneous T cell lymphoma (CTCL) patients with blood involvement was inferior to those without blood involvement ($P = 0.051$).

“mycosis cells” in ~20% of mycosis fungoides patients.^{10,14,18,32,33,34} Correlation with other clinical and pathologic findings and prognosis have been addressed, however, in only a few of these studies.¹⁶⁻¹⁹ Our study affirms that the frequency of blood involvement is directly correlated with the type of skin lesion and other features of advanced stage. Tumor cell morphology did not differ between the erythrodermic (T4) or classic Sézary syndrome patients and the T2/T3 mycosis fungoides patients except that lymphocytosis and the mixed-cell type was more prevalent in the T4 patients. The presence of circulating tumor cells in a univariate analysis was associated with an inferior survival; however, multivariate analysis established that whereas both skin class and age >50 years were independent risk factors in this series, peripheral blood involvement was not. When T2 and T3 skin disease patients were evaluated separately, blood involvement appeared to affect survival adversely.

When Lutzner and co-workers described the small-cell variant Sézary cell, no prognostic significance was attributed to cell size. In the B cell lymphomas, nearly all studies show that large cell size is associated with a more aggressive natural history.³⁵ In this study, we demonstrated that CTCL patients with >20% of large convoluted cells (mixed-cell type) have shorter survival than those with blood involvement having predominantly small cells.

The mixed-cell type was strongly associated with features of aggressive disease, including lymph node effacement, visceral involvement, increased proportions of convoluted cells, and higher absolute concentrations. Vonderheid and colleagues recently reported that survival in a group of erythroderma patients was more closely related to the proportion of large convoluted cells (15 to 20 μm) than to the relative or absolute number of convoluted cells.¹⁹ Our data support earlier results of Vonderheid and colleagues¹⁷ in that

Table 7. Pretreatment Characteristics and Their Relation to Survival for Group I Patients (n = 105)

Characteristic and Description	No. of Patients in Analysis	Group (Observed/Expected)*	Univariate P Value
Age (<50 v ≥50)	101	Age <50 (7/15.54)	.003

CTCL, cutaneous T cell lymphoma.

*Observed/expected is the observed number of failures in the defined group divided by the expected number of failures in the group. The expected value is calculated using the standard procedure described by Mantel,³¹ under the null hypothesis that there exists no difference between the groups.

†All pair-wise comparisons between different T categories were significant to $P < .05$ except T1 v T2 ($P = .78$) and T3 v T4 ($P = 0.75$). For multivariate analysis, the T1 and T2 patients were combined; similarly, the T3 and T4 patients were combined.

the number of circulating tumor cells also had an effect on outcome. In our series, in addition to cell size, lymphocytosis had an adverse effect on survival. This effect was most clearly seen in a survival advantage for small-cell patients with normal lymphocyte concentrations. For patients with elevated lymphocyte counts, survival was poor irrespective of cell size.

Occasional cells with electron-microscopic morphology similar to that of Sézary cells are frequently found in the skin and blood of patients with benign dermatoses.³⁶⁻³⁸ These findings are not surprising since CTCL represents a malignancy of mature helper T cells, and normal as well as reactive T cells may resemble their malignant counterpart morphologically.¹ In our series, patients with benign disorders did not have cells with the degree of the nuclear abnormalities and density of chromatin found in CTCL. No patient with a benign skin disorder and no normal individual met our criteria for CTCL cell infiltration. Occasional patients with CTCL had increased numbers of cells with minor nuclear irregularities. These patients were predominantly from advanced disease subsets. Determination of whether the lymphoid cells in these patients represent reactive cells or circulating tumor cells with a relatively bland morphology must await techniques that can clearly establish clonality and measure the extent of the infiltration. Use of DNA probes for the β T cell receptor gene has demonstrated clonal rearrangements in tissues histologically involved with CTCL.^{39,40} With the sensitivity to detect 1% to 5% tumor cells in a population, DNA probes also offer promise of detecting CTCL cells in apparently benign lymph nodes with

dermatopathic lymphadenopathy⁴⁰ and among circulating lymphocytes. In this study, E rosette cytology did not increase the sensitivity of detecting peripheral blood involvement, since only four patients had a positive ERC after a negative or suspicious smear was found. We previously reported similar results with electron microscopy,²⁸ and probably neither expensive procedure would increase the yield of positive findings. Cytogenetic analysis clearly does increase the sensitivity of detection, and flow cytometry may detect small numbers of cells when aneuploidy is present.^{13,15} The prognostic significance of detecting small numbers of such cells is unclear, however.

Detailed examination of peripheral blood smears is a noninvasive, inexpensive means of assessing extracutaneous involvement by CTCL. In nonerythrodermic CTCL, our results suggest that identification of blood involvement may be useful in identifying a small subset of patients with inferior survival while they are receiving current therapy. Because blood involvement is nearly universal in erythrodermic CTCL, examination of the peripheral blood smear can also be helpful in confirming a diagnosis of CTCL in patients with chronic erythroderma and nondiagnostic skin biopsies. In addition, assessment of the cell size distribution of the circulating CTCL cells will be useful in distinguishing patients with small-cell type whose course is relatively indolent from patients with the more aggressive mixed-cell type.

Abnormal Prothrombin in the Plasma of Rats Carrying Hepatic Tumors

By D.V. Shah, J.A. Engelke, and J.W. Suttie

Vitamin K is required for the posttranslational formation of γ -carboxyglutamyl residues in a number of plasma clotting factors. Interference with vitamin K action results in the appearance of abnormal (des- γ -carboxy) forms of prothrombin in human plasma. Vitamin K-sufficient patients with primary hepatocellular carcinoma also secrete significant quantities of abnormal prothrombin; this response has now been studied in a rat model. Normal Buffalo strain rats had 9 $\mu\text{g/mL}$ of circulating plasma abnormal prothrombin, whereas Buffalo strain rats carrying the transplantable Morris hepatoma tumor no. 7777 had 33 $\mu\text{g/mL}$ at 3 weeks

after transplant. Vitamin K-dependent carboxylase activity was normal in the liver of these rats, but very low in the tumor tissue. Rats carrying Morris hepatoma tumors no. 9618A and 5123D did not secrete significant amounts of abnormal prothrombin. Carboxylase activity in these tumors was 15 times that of the 7777 tumor. The data suggest that the secretion of abnormal prothrombin by hepatocellular tumors is the result of normal expression of the prothrombin gene by those tumors and a failure of the tumor to express the carboxylase gene.

© 1987 by Grune & Stratton, Inc.

VITAMIN K is required for the synthesis of clotting factors II (prothrombin), VII, IX, and X, and plasma proteins S, C, and Z.¹ The vitamin functions as a cofactor in the posttranslational carboxylation of specific glutamyl residues in microsomal protein precursors to form γ -carboxyglutamyl (Gla) residues in biologically active completed proteins.² In the absence of vitamin K or when its action is antagonized by coumarin anticoagulants, des- γ -carboxy or "abnormal" forms of prothrombin are excreted into human³ and bovine⁴ plasma. These proteins differ from prothrombin in their failure to adsorb to insoluble barium salts, to bind calcium ions in solution, or to demonstrate the Ca^{2+} -dependent phospholipid association needed for normal physiological activation.⁵ The abnormal prothrombin will, however, yield thrombin⁶ when treated with a nonphysiological activator such as the protease from *Echis carinatus* venom.⁷

A survey⁸ of the existence of abnormal prothrombin in the plasma of anticoagulant-treated species other than the human or bovine reported substantial amounts in chick, small amounts in rat and mouse, and insignificant amounts in hamster, guinea pig, rabbit, and dog plasma. The basis for the wide species variation in the excretion of abnormal prothrombin has not been determined. Development of a more sensitive amidolytic assay for rat prothrombin⁹ has shown that plasma from vitamin K-deficient or warfarin-treated rats contains a non- BaSO_4 adsorbable (undercarboxylated) pool of prothrombin that is equivalent to between 5% and 10% of the normal plasma prothrombin concentration. Conformation-specific antibodies directed toward this class of human prothrombin have been developed¹⁰ and used to

demonstrate that the concentration of abnormal prothrombin is very low in normal adults, increases substantially with oral anticoagulation or vitamin K deficiency, and is slightly increased in many patients with liver disease.¹¹

More recently, it was reported¹² that abnormal prothrombin was more drastically increased in patients with primary hepatocellular carcinoma than in other hepatic disorders and that this response was not due to vitamin K deficiency. The molecular basis for increased levels of abnormal prothrombin in diagnosed cases of hepatic carcinoma has not been established. The response has now been studied using the tumor-bearing rat as a model.

MATERIALS AND METHODS

Treatment of animals. Male rats of the Buffalo strain, weighing 50 to 60 g, were maintained on Purina laboratory chow. Vitamin K-supplemented rats were administered 1 mg of phyloquinone (Konakion, Hoffman-La Roche, Nutley, NJ) intramuscularly (IM) each week for 3 consecutive weeks. Morris hepatoma tumors no. 7777, 5123D, or 9618A were transplanted by disrupting ~1 g of tumor tissue in 5 mL of sterile Dulbecco's modified Eagle's medium (DMEM) and giving a 0.5 mL injection in each hind leg of a recipient rat.¹³

Prothrombin and abnormal prothrombin assay. Rat blood for these amidolytic assays was collected by cardiac puncture in 0.15 mol/L of potassium oxalate (10% vol/vol), centrifuged for 20 minutes at 2,000 g at 4 °C, and individual plasma samples were stored at -30 °C. Vitamin K-dependent clotting factors were adsorbed from individual plasma samples by adding 35 mg/mL of citrate-washed BaSO_4 and stirring for 1 hour at 0 °C. Prothrombin and abnormal prothrombin concentrations were determined by assay of thrombin-catalyzed amidolysis of the chromogenic peptide substrate, H-D-Phe-Pip-Arg-pna (S2238 from Kabi Diagnostics, Stockholm) as previously described.⁹ Plasma prothrombin (normal) was measured with the chromogenic substrate after activation with a calf serum factor mix⁹ and commercial thromboplastin (Thromboplastin, Sigma Diagnostics, St Louis), and total normal plus abnormal prothrombin was measured after activation with *E carinatus* venom. Abnormal prothrombin was measured by activation of the BaSO_4 -adsorbed plasma with *E carinatus* venom (Sigma).

Vitamin K-dependent carboxylation. Buffalo strain rats carrying the transplantable Morris hepatoma tumors were used when they weighed 160 to 175 g. When administered, sodium warfarin (5 mg/kg) was given by intraperitoneal (IP) injection 18 hours prior to killing. Holtzman strain rats were used as normal controls in carboxylase assay so that the enzyme activities from different rat strains could be standardized. Rats were killed, and a crude microsomal preparation of both liver and tumor tissue was prepared as previously described,¹⁴ except that rats were not fasted. A Triton

X-100 (RPI, Elk Grove Village, IL) solubilized preparation of microsomes equivalent to 0.5 g of liver or 1.0 g of excised tumor mass per milliliter were obtained and incubated at 17 °C for 30 minutes to determine the vitamin K-dependent incorporation of $H^{14}CO_3$ into the substrate Boc-Glu-Glu-Leu-OMe (BaChem Fine Chemicals, Torrance, CA).^{15,16}

RESULTS

Absorption with $BaSO_4$ is capable of removing all but a small fraction of prothrombin in the plasma of vitamin K-sufficient rats.⁹ When non- $BaSO_4$ adsorbable prothrombin (abnormal prothrombin) was measured in the plasma of Buffalo strain rats carrying three different Morris hepatoma tumors, a significant increase was seen in the rats carrying the most rapidly growing tumor (Table 1). Buffalo rats carrying the transplantable Morris hepatoma tumor no. 7777 had an approximate fourfold increase in circulating abnormal prothrombin as compared with normal Buffalo rats. Partially carboxylated forms of prothrombin are present following anticoagulation,^{17,18} and these forms differ in their ability to adsorb to barium salts.¹⁹ $BaSO_4$ treatment removed 97% of the thromboplastin-activatable prothrombin in normal plasma but only 85% of this prothrombin species in the plasma of tumor-bearing Buffalo strain rats. These data suggest that a significant amount of partially carboxylated prothrombin is also secreted in tumor-bearing Buffalo strain rats. The concentration of plasma abnormal prothrombin was very much dependent on the period of time after tumor transfer. As shown in Fig 1, normal Buffalo strain rats had 8 to 9 $\mu g/mL$ of circulating plasma abnormal prothrombin, whereas Buffalo strain rats carrying the transplantable Morris hepatoma tumor no. 7777 had 10 $\mu g/mL$ at 2 weeks and 33 $\mu g/mL$ at 3 weeks after transplant. High concentrations of plasma abnormal prothrombin were noted only near the end of the transplant period and presumably reflected tumor mass.

In an attempt to discover the cause of the abnormal prothrombin secretion in tumor-bearing rats, liver and tumor tissue vitamin K-dependent carboxylase activities were determined. Carboxylase activity was slightly higher in the livers of Buffalo strain rats carrying the transplantable Morris hepatoma tumor no. 7777 as compared with normal Buffalo strain rats (Fig 2), but the activity of this enzyme in tumor tissue was <5% of that in normal liver tissue. Liver vitamin K-dependent carboxylase activity is increased by a

Fig 1. Appearance of abnormal prothrombin after transplant of Morris hepatoma tumor no. 7777. Plasma samples from each rat were assayed after $BaSO_4$ adsorption as described in the Materials and Methods section. Values are mean $\pm$ SEM for three to six rats per group.

vitamin K deficiency,¹⁴ and carboxylase activity in both normal and tumor-bearing rats and in tumor tissue was depressed when the rats were supplemented with vitamin K (Fig 2). Vitamin K-supplemented Buffalo rats carrying the transplantable Morris hepatoma tumor no. 7777 had the same fourfold increase in circulating abnormal prothrombin as compared with K-supplemented normal Buffalo rats (data not shown) as is shown in Table 1, indicating that the elevated levels of abnormal prothrombin in circulation were not due to vitamin K deficiency.

The response of normal rats to vitamin K deficiency or warfarin administration is an increase in the activity of the liver microsomal vitamin K-dependent carboxylase¹⁴ and an increase in the concentration of microsomal prothrombin precursors.^{8,20} The livers of rats carrying the no. 7777 tumor demonstrated the same responses, but warfarin administration had no influence on vitamin K-dependent carboxylase activity or microsomal prothrombin precursor concentration of the tumor tissue (Figs 3 and 4).

Rats carrying transplantable Morris hepatoma tumors no.

Table 1. Plasma Normal and Abnormal Prothrombin Concentrations in Tumor-Carrying Buffalo Rats

Tumor No.	Weeks Between Transfer	Plasma Prothrombin Concentrations ($\mu g/mL$)

		Before $BaSO_4$	After $BaSO_4$ *	Before $BaSO_4$ †	After $BaSO_4$
No tumor (12)	—	103 $\pm$ 3	9 $\pm$ 1	98 $\pm$ 2	3 $\pm$ 1
7777 (9)	3–4	113 $\pm$ 2	34 $\pm$ 4‡	100 $\pm$ 2	15 $\pm$ 2
5123D (12)	6–8	110 $\pm$ 3	12 $\pm$ 1	112 $\pm$ 3	11 $\pm$ 1
9618A (9)	8–9	119 $\pm$ 3	11 $\pm$ 1	110 $\pm$ 4	5 $\pm$ 1

Plasma for analysis was obtained at the time of tumor transfer. The three different tumor strains have different growth rates, and were transferred when the mass of the tumors was similar. Values are mean $\pm$ SEM for the number of animals indicated in parentheses.

*"Abnormal" prothrombin.

†"Normal" prothrombin.

‡Significantly higher ($P < .01$) than the other three treatments.

Fig 2. Vitamin K-dependent carboxylase activity in liver and tumor tissue of rats. Normal and tumor-bearing Buffalo strain rats were killed 3 weeks after transplant of Morris hepatoma tumor no. 7777. The rats were fed a commercial laboratory chow diet and administered either 1 mg of phyloquinone or saline each week. Vitamin K-dependent carboxylase activity was determined as described in the Materials and Methods section. Data were obtained on different days, and the carboxylase activity of two vitamin K-sufficient Holtzman strain rats assayed each day was used as the 100% control activity. Values are mean $\pm$ SEM for 6 to 18 rats in each group. (A) Chow diet only; (B) vitamin K supplement.

5123D and 9618A did not secrete significant amounts of abnormal prothrombin (Table 1). Vitamin K-dependent carboxylase activity and microsomal prothrombin precursor concentration in the livers of normal Buffalo strain rats and the livers of these rats carrying transplantable Morris hepatoma tumors no. 5123D and 9618A were compared. Similar liver carboxylase activities and microsomal precursor con-

Fig 3. Effect of warfarin administration on microsomal vitamin K-dependent carboxylase activity in liver and tumor tissue. Normal rats and rats carrying a Morris hepatoma tumor no. 7777 for 3 weeks were administered either warfarin (5 mg/kg, intraperitoneally) or saline 18 hours before being killed. Vitamin K-dependent carboxylase activity was determined as described in the Materials and Methods section. Carboxylase activity of four normal Holtzman strain rats was used as the 100% control activity. Values are mean $\pm$ SEM for three to four rats in each group.

Fig 4. Effect of warfarin administration on microsomal prothrombin precursor concentration in liver and tumor tissue. Microsomal precursor concentration was determined as described in the Materials and Methods section. Other conditions were as described in the legend to Fig 3.

centrations were found (Fig 5) in rats carrying these two tumors. Activity of the vitamin K-dependent carboxylase in the tumor tissue from these rats was, however, ~20% to 30% of that in the host rat liver (Fig 5). This activity was ~15 times higher than the activity observed in the no. 7777 tumor tissue shown in Fig 2. The microsomal prothrombin precursor concentration in the liver of the rats carrying the three

Fig 5. Vitamin K-dependent carboxylase activity and microsomal prothrombin precursor concentrations in liver and tumor tissue of rats. Normal and tumor-bearing rats were killed 6 to 8 weeks or 8 to 9 weeks after transplantation of Morris hepatoma tumor no. 5123D or 9618A. Assays were as described in Figs 3 and 4. Data are from a single experiment representative of three experiments. Values are mean $\pm$ SEM for three to six rats in each group.

different Morris hepatoma tumors was, however, comparable (Figs 4 and 5), and liver vitamin K-dependent carboxylase activity was somewhat higher in rats carrying the no. 7777 tumor as compared with the 5123D or 9618A tumor (compare Figs 3 and 5).

DISCUSSION

Liebman and colleagues¹² detected elevated abnormal prothrombin in the serum of patients with biopsy-confirmed hepatocellular carcinoma and established that this elevation does not reflect a vitamin K deficiency in these patients. The data of the present study demonstrate that the rat is a suitable model for studying this response. Adsorption of oxalated plasma with BaSO₄ will remove almost all normal prothrombin,⁹ and increases in venom-generated thrombin above the background represent secretion of abnormal prothrombin. The plasma of rats carrying one of three strains of Morris hepatoma tumors contained significant amounts of abnormal prothrombin.

These data are consistent with the hypothesis that the tumors that increase circulating abnormal prothrombin are those that are capable of expressing the prothrombin gene but that have lost the ability to express significant levels of the vitamin K-dependent carboxylase enzyme. This view is supported by the low concentrations of this enzyme measured in the no. 7777 tumor tissue as compared with much higher concentrations in the 5123D and 9618A lines, which secreted less abnormal prothrombin. It is also possible that the no. 7777 tumor line contains an inhibitor of the enzyme

or that turnover rate of the enzyme has been substantially increased. The failure of the no. 7777 tissue to increase carboxylase activity or microsomal prothrombin precursor concentrations following warfarin administration, however, also suggests a low level of expression of this gene. Normal rat liver responds to warfarin administration with an increase in both precursor concentration and enzyme activity^{14,20} and is evidence^{14,21,22} that association of the precursor with the enzyme is responsible for these changes. The delay in abnormal prothrombin appearance following transfer of the Morris hepatoma tumors is consistent with the need for a significant tumor mass to develop before this product is seen in plasma.

Vitamin K-dependent carboxylase activity was consistently elevated in the liver of rats carrying tumors. This may reflect the response of carboxylation activity to des- γ -carboxy forms of vitamin K-dependent clotting factors or other unknown factors present in plasma of hypoprothrombinemic animals.²³⁻²⁷ Availability of rat hepatoma lines that do secrete large amounts of abnormal prothrombin in the absence of carboxylation provides a valuable tool with which to study this response.

ACKNOWLEDGMENT

We are indebted to Dr H.C. Pitot of the McArdle Laboratories of the University of Wisconsin-Madison for the donation of tissues from tumor-carrying experimental animals for use in this study, and to W.S. Kennan for technical assistance in obtaining tissues for the study.

Chromosome Abnormalities in AIDS-Associated Lymphadenopathy

By M. Lita Alonso, Mark E. Richardson, Craig E. Metroka, Janet A. Mouradian,
Prasad R.K. Koduru, Daniel A. Filippa, and R.S.K. Chaganti

Cytogenetic studies were performed on direct and 24-hour culture preparations of eight lymph node biopsies from seven patients with acquired immunodeficiency syndrome (AIDS) or AIDS-related complex (ARC)-associated lymphadenopathy in whom histological evidence of lymphoma was not detected. Three of these seven had chromosomal abnormalities, including chromosome instability in one and clonal chromosomal abnormalities in two; one of the latter was a t(8;14)(q24;q32). The remaining five showed normal karyotypes. Epstein-Barr virus (EBV) titers were elevated in all three patients that exhibited chromosome abnormali-

ties, two of whom later developed malignant lymphoma. A control group of five patients with reactive lymphadenopathy not associated with AIDS failed to reveal chromosomal aberrations, but elevated EBV titers were present in two. These data are consistent with current views on the role of EBV and chromosome change in the development of lymphoma in immunodeficient states and suggest that karyotypically abnormal AIDS-related lymphadenopathy represents a prelymphomatous proliferation.

© 1987 by Grune & Stratton, Inc.

THE ACQUIRED immunodeficiency syndrome (AIDS) comprises a group of clinical presentations that have recently emerged as an epidemic among subgroups of homosexual males, intravenous (IV) drug users, blood transfusion recipients, and others. *Pneumocystis carinii*, cytomegalovirus (CMV) and other opportunistic infections, autoimmune phenomena, generalized lymphadenopathy, lymphoma, and Kaposi's sarcoma (KS) have characterized this disorder.¹⁻⁵ A prodromal phase consisting of fever, weight loss, and lymphadenopathy frequently precedes opportunistic infections. Lymphopenia, cutaneous anergy, decreased in vitro responsiveness to mitogens, decreased T helper cells, and inversion of the T helper/T suppressor ratio are common immunological abnormalities in AIDS.⁶⁻⁸ The human T cell lymphotropic virus (HTLV-III) has recently been shown to play an etiologic role in AIDS.⁹⁻¹² Currently, patients in high-risk groups for AIDS with generalized lymphadenopathy but lacking evidence of KS or opportunistic infection are classified as having the AIDS-related complex (ARC). The types of neoplasms seen in this disorder are similar to those seen in posttransplantation immunosuppressed patients^{13,14} and include a Burkitt's-like undifferentiated lymphoma with characteristic rearrangements involving chromosomes 8, 14, and 22 and a probable Epstein-Barr virus (EBV)-related etiology.¹⁵⁻¹⁷ Although current evidence suggests that the lymphomas in immunosuppressed states arise among polyclonal lymphoid proliferations by selective expansion of monoclonal cells characterized by specific chromosome rearrangements, the cytogenetic nature of the prelymphomatous proliferations is essentially unknown. To address this question, we performed cytogenetic analysis of lymph node biopsies from seven patients with generalized lymphadenopathy arising in a clinical spectrum of AIDS (two cases) or ARC (five cases). For comparison, we also studied a control group of five patients with reactive lymphadenopathy not associated with AIDS or ARC. Our results show that chromosome instability and clonal changes characterize only AIDS or ARC-associated proliferations.

MATERIALS AND METHODS

All patients had lymphadenopathy, which was generalized in the seven patients with AIDS or ARC (group I, Table 1) and localized in five who did have AIDS or ARC (group II). Lymph node histology and laboratory data of all patients studied are summarized in Table 1. All seven group I patients had evidence of an immune dysfunction

based on markedly depressed lymphoproliferative responses to a variety of mitogens and antigens. All group I cases were in high-risk groups for AIDS. Those classified as having AIDS had KS or an opportunistic infection, and those classified as having ARC did not. Chromosome preparations were made from single-cell suspensions of freshly obtained lymph node biopsies. The cells were incubated 1 to 3 hours in colcemid (final concentration of 0.1 µg/mL) or were cultured for 24 hours in RPMI 1640 medium supplemented with 20% fetal bovine serum (FBS) and the antibiotic penicillin-streptomycin. Colcemid was added to the cultures during the final hour. Cell harvest and chromosome preparation were made following conventional methods using 0.075 mol/L of potassium chloride as the hypotonic solution and methanol/acetic acid 3:1 as the fixative. Karyotyping was performed from trypsin-Giemsa or quinacrine-banded preparations. All histologic specimens were reviewed, and lymphomas were classified using the Working Formulation.¹⁸

RESULTS

Of the 13 nodes studied, three showed chromosomal abnormalities [patients 1 (first biopsy), 3, and 6—group I, Table 1]. Biopsies from patients 1 and 3 exhibited mixtures of normal and clonally abnormal cells. In biopsy 1 of patient 1, of the 30 cells analyzed, 27 were normal (46,XY or hypodiploid due to random loss of chromosomes) and three had rearranged chromosomes. The chromosomal complements of the latter were the following respectively: (a) 46,XY,t(8;14)(q24;q32), (b) 46,X,-Y,t(8;14)(q24;q32), +mar1, and (c) 43,X,-Y,-8,-14,-16,-19,+8q,-, +mar1. The mar1 chromosome was comprised of the entire long arm of

ARC, AIDS-related complex; CMV, cytomegalovirus; EBV, Epstein-Barr virus; KS, Kaposi's sarcoma; ND, not done.

*Hypodiploid chromosome numbers represent random chromosome loss due to cell rupture during preparation.

chromosome 1. Thus, the presence of the 8q- and mar1 chromosomes in the third cell indicates that it also belongs to the same abnormal clone as the other two cells. The absence of the 14q+ chromosome in it probably represents random loss of this chromosome, only a single copy of chromosome 14 being present in this cell. In the biopsy from patient 3 (Table 1), of 20 cells analyzed, 18 were normal (46,XY or hypodiploid due to random loss of chromosomes) and two had a small acrocentric marker chromosome in addition to an otherwise normal chromosome complement. The two cells with the marker chromosome thus identify a clonal proliferation with the karyotype 47,XY,+mar1. The derivation of mar1 in these cells could not be determined due to its nonspecific banding pattern. Among the cells analyzed from the biopsy of patient 6, nonspecific chromosome and chroma-

tid breakage was seen in 3 of 16 (19%) (Table 1). The remaining ten nodes including five each from groups I and II revealed only normal chromosomal complements (46,XY or hypodiploid due to random loss of chromosomes).

EBV titers, shown in Table 1, were elevated in two group II patients with negative monospot tests. No chromosome abnormalities were present in biopsies from these patients. EBV titers were elevated in six of the seven group I patients. The patient with the highest EBV titer (patient 7, group I, Table 1) lacked cytogenetic aberrations. A subsequent non-Hodgkin's lymphoma developed in patients 1, 4, and 6. The lymphoma in patient 1 was classified as immunoblastic B cell type, and in patient 4 was classified as diffuse large cell type. Histologic slides showing lymphoma in case 6 were unavailable for review for classification.

DISCUSSION

The pattern of lymphoma development in AIDS is strikingly similar to that in two other immunodeficiency states, namely, posttransplantation immunodepression and X-linked lymphoproliferative syndrome.¹³ Lymphomagenesis in both disorders is increasingly recognized to be linked to EBV infection.¹⁹ In these cases, a polyclonal proliferation of B cells, probably initiated by viral infection, is suggested to lead to monoclonal expansion of malignant cells characterized by specific chromosome rearrangements that bring about juxtaposition of the *c-myc* oncogene and the immunoglobulin loci, resulting in *c-myc* deregulation.²⁰⁻²² Such a model implies that the proliferating polyclonal cells which may be preneoplastic are genetically unstable and exhibit chromosome rearrangements that include the abovementioned lymphoma-specific ones.²³ Cytogenetic data pertaining to this proliferation have not been available until now.

In our study, three of eight reactive lymph nodes associated with AIDS or ARC (group I) revealed chromosome abnormalities. All three patients, two of whom later developed lymphoma also had high EBV titers. Another group I patient with high EBV titers eventually developed a non-

Hodgkin's lymphoma, and two group II patients with high titers remain alive and well 12 to 19 months following diagnosis. We did not detect a chromosome abnormality in the lymph node biopsies from these latter three patients, suggesting that EBV infection may precede the appearance of cytogenetic abnormalities. Unfortunately, tissues from lymphomas were not available to us for cytogenetic analysis. In contrast, five reactive lymphadenopathies unassociated with AIDS or ARC (group II) failed to reveal chromosome aberrations despite elevated EBV titers in two.

The cytogenetic evidence presented here strongly suggest that the lymphadenopathies of AIDS or ARC patients represent prelymphomatous proliferations, which is in accord with histopathological evidence for the development of non-Hodgkin's lymphoma correlated with AIDS lymphadenopathy presented by other investigators.^{14,24-27} EBV infection may be related to the chromosome breakage, which precedes lymphoma development. Further cytogenetic and molecular studies of AIDS-related lymphadenopathy should clarify the significance of this proliferation to lymphoma development.

Sodium Fluoride Mimics Effects of Both Agonists and Antagonists on Intact Human Platelets by Simultaneous Modulation of Phospholipase C and Adenylate Cyclase Activity

By Joachim Kienast, Jef Arnout, György Pfliegler, Hans Deckmyn, Bernard Hoet, and Jos Vermynen

Using intact human platelets, we studied the effect of sodium fluoride (NaF) on platelet aggregation and release reaction and correlated the functional changes to intracellular events specific for either agonist-induced or antagonist-induced platelet responses. At lower concentrations, with a peak activity between 30 and 40 mmol/L, NaF induced aggregation and release of adenosine 5'-triphosphate (ATP) that was associated with increased formation of inositol phosphates, a rise in cytosolic free Ca^{2+} , and phosphorylation of 20-kd and 40-kd proteins. At NaF concentrations >40 mmol/L, aggregation and ATP release decreased dose-dependently in parallel with a decrease in Ca^{2+} mobilization, whereas neither inositol phosphate formation nor 40-kd protein phosphorylation was reduced. At these concentrations, NaF caused a dose-dependent transient rise in platelet cyclic adenosine 3',5'-monophosphate (cAMP) levels that was sufficient to account for the

observed reduction in Ca^{2+} mobilization, aggregation, and ATP release. Stimulated cAMP levels started declining rapidly within 30 seconds of addition of NaF, however. Similarly, prostacyclin (PGI_2)-induced cAMP accumulation was temporarily enhanced but subsequently suppressed by NaF, suggesting either stimulation of a cAMP phosphodiesterase or delayed inhibition of adenylate cyclase. Evidence for the latter was provided by the finding that NaF pretreatment of platelets resulted in partial inhibition of PGI_2 -stimulated cAMP formation in the presence of the cAMP phosphodiesterase inhibitor 3-isobutyl-1-methyl-xanthine (MIX). We conclude that NaF exerts a dual (stimulatory and inhibitory) effect on adenylate cyclase in intact platelets that is accompanied by simultaneous activation of a phosphoinositide-specific phospholipase C; in addition, a cAMP phosphodiesterase may be activated.
© 1987 by Grune & Stratton, Inc.

PLATELETS REACT to a variety of biologically active substances (agonists) with partial or full activation characterized by shape change, release of granule contents, and aggregation. Conversely, other agents (antagonists) such as prostacyclin (PGI_2) or prostaglandin E_1 induce a state of reduced responsiveness to agonists.^{1,2} The nature of a platelet response initiated by receptor occupancy depends on the selective coupling of a particular receptor to at least two major messenger-generating systems. One involves phospholipase C-catalyzed hydrolysis of membrane inositol phospholipids, Ca^{2+} mobilization, activation of protein kinase C, and arachidonic acid liberation, whereas the other is related to the formation of cyclic adenosine 3',5' monophosphate (cAMP) catalyzed by adenylate cyclase.^{3,4} Adenylate cyclase activity is subject to regulation by two distinct guanine nucleotide-binding proteins (also referred to as G or N proteins) that couple the enzyme to specific membrane receptors and allow receptor expression as either N_s -mediated stimulation of N_i -mediated inhibition of its catalytic subunit.⁵⁻⁷ In addition, more recent evidence gave rise to the hypothesis that a guanine nucleotide-binding protein might also constitute the link that couples stimulatory platelet receptors to phospholipase C activation and/or Ca^{2+} mobilization.⁸⁻¹⁰

Fluoride activates N proteins by promoting the dissociation of their subunits.^{5,11-13} In isolated platelet membranes, sodium fluoride (NaF) both stimulates and inhibits adenylate cyclase through activation of N_s and N_i respectively.^{12,13} Conflicting results have been reported regarding the influence of NaF on intact platelets. Enhanced cAMP formation has been described¹⁴ as have NaF-induced mobilization of cytosolic free Ca^{2+} , platelet aggregation, and serotonin release.¹⁵⁻¹⁷ These findings led us to investigate the effects of NaF on platelet function further, with particular attention to intracellular regulatory processes. In this article we demonstrate that NaF has a concentration-dependent, biphasic effect on platelet activation as a result of simultaneous modulation of phospholipase C and adenylate cyclase

activity. We suggest that NaF-sensitive N proteins are not only involved in the regulation of adenylate cyclase but may also play a role in phospholipase C activation.

MATERIALS AND METHODS

Reagents. [2,8- ^3H]Adenine (17.7 Ci/mmol) and [8- ^{14}C] cAMP phosphate (45.1 mCi/mmol) were obtained from New England Nuclear (Boston). Carrier-free [^{32}P]orthophosphate (40 mCi/mL in aqueous solution), myo-[2- ^3H]inositol (13.8 Ci/mmol), and quin 2 acetoxymethyl tetraester (Quin 2/AM) came from Amersham International (Amersham, England). Insta-Gel II was from Packard Instrument B.V. Chemical Operations (Groningen, The Netherlands). AG 50W-X4 cation exchange resin (200 to 400 mesh) was obtained from Bio-Rad Laboratories (Richmond, CA), and Dowex 1x8 anion exchange resin (200 to 400 mesh) was obtained from Fluka (Buchs, Switzerland). Sepharose 2B was from Pharmacia Fine Chemicals (Uppsala, Sweden). Apyrase, arachidonic acid and adenosine 5'-diphosphate came from Sigma Chemical (St Louis) and 3-isobutyl-1-methyl-xanthine (MIX) from Janssen Chimica (Beerse, Belgium). Platelet-activating factor (1-*O*-hexadecyl-2-acetyl-*sn*-glyceryl-3-phosphorylcholine) was from Boehringer (Mann-

heim, FRG), A23187 from Calbiochem-Behring Corp (San Diego), bovine thrombin from Roche (Brussels, Belgium), and collagen from Hormon-Chemie (Munich, FRG). PGI₂ was obtained from Upjohn (Kalamazoo, MI). Luciferin/luciferase reagent came from Chrono-Log Corp (Havertown, PA) and NaF from Baker Chemical (Phillipsburg, NJ). Bovine serum albumin (BSA) was from Organon Teknika (Boxtel, the Netherlands). CV-3988 (rac-3-(*N*-octadecyl-carbamoyloxy)-2-methoxypropyl 2-thiazolioethyl phosphate) was kindly provided by Takeda Chemical Industries (Osaka, Japan). All other chemicals were of analytical grade obtained from various sources.

Preparation of platelet-rich plasma. Blood was obtained by clean venipuncture of healthy volunteers who denied having taken any drugs during the previous 2 weeks. Anticoagulants used were either 0.1 vol of 106 mmol/L of trisodium citrate, 0.03 vol of 0.3 mol/L of EDTA, or 0.14 vol of ACD buffer (85 mmol/L of trisodium citrate, 71 mmol/L of citric acid, 111 mmol/L of dextrose, pH 4.5) as specified below. Platelet-rich plasma (PRP) was prepared by centrifugation at 150 g for 10 minutes at 20 °C.

Stimulation of platelets by NaF. For stimulation of platelets by NaF, 0.1 vol of prepared reaction mixtures containing NaF in distilled water in the appropriate amount to yield final concentrations of NaF between 10 and 100 mmol/L as indicated was added to 0.9 vol of platelet suspensions. To preclude any influence by Na⁺ or by changes in osmolarity, the reaction mixtures were made up with NaCl to give 1-mol/L solutions; 0.1 vol of 1 mol/L of NaCl in distilled water was added to controls. These principles were retained throughout all experimental procedures.

Platelet aggregation and ATP release. Aliquots of 0.45 mL of citrated PRP together with 0.05 mL of reconstituted luciferin/luciferase reagent (40 mg in 1 mL of sterile water) were placed into aggregometer cuvettes and preincubated while being stirred for 1 minute at 37 °C in a Lumi-Aggregometer Model 400 (Chrono-Log, Havertown, PA). Then 0.055 mL of NaF/NaCl-containing reaction mixtures was added. Aggregation and adenosine triphosphate (ATP) release were monitored over 10 minutes by parallel recording of light transmission and luminescence displayed on a dual-channel chart recorder. The luminescence signal was calibrated by addition of a known amount of ATP at the end of each experiment. Part of the aggregation studies was performed in an Elvi 840 dual-channel aggregometer (Elvi Logos, Milan). Threshold aggregating concentrations were defined as minimal concentrations of inducers that caused irreversible platelet aggregation within 2 minutes of addition to stirred PRP. Inhibitors (apyrase, acetylsalicylic acid, CV-3988) were added 3 minutes prior to platelet stimulation.

Measurement of [³H]inositol phosphates. NaF-induced changes in inositol phosphate formation were measured as described, with minor modifications.^{18,19} PRP obtained from 100 mL of freshly drawn blood anticoagulated with EDTA was centrifuged at 800 g for 10 minutes at 20 °C. The platelet pellet was resuspended in 3 mL of a modified Tyrode's solution-HEPES buffer (134 mmol/L of NaCl, 12 mmol/L of NaHCO₃, 2.9 mmol/L of KCl, 0.34 mmol/L of Na₂HPO₄, 5 mmol/L of HEPES, 5 mmol/L of glucose, and 1 mmol/L of EGTA pH 6.8). For labeling, the platelet suspension was incubated with myo-[2-³H]inositol (66 μCi/mL) for 3 hours at 37 °C. Platelets were then washed in 30 mL of buffer without EGTA and finally resuspended in modified Tyrode's solution-HEPES buffer (pH 7.4 at 37 °C) containing 1 mmol/L of CaCl₂ and 1 mmol/L of MgCl₂ instead of EGTA. LiCl 10 mmol/L was added to inhibit the degradation of inositol 1-phosphate to free inositol.²⁰ The final platelet concentration was adjusted to 8 × 10⁸/mL. Samples of 0.5 mL were transferred into aggregometer cuvettes and preincubated while being stirred at 37 °C for 1 minute. Then 0.055 mL of NaF/NaCl-containing reaction mixtures was added, and the incubation was continued for varying times as indicated. The reaction

was stopped by transferring the samples into 1.88 mL of chloroform/methanol/HCl (100:200:2, vol/vol). For phase separation of the extract, 0.62 mL of chloroform and 0.62 mL of water were added. After thorough mixing, the samples were centrifuged at 800 g for 10 minutes. Then 1.5 mL of the upper phase containing the water-soluble inositol phosphates was diluted in 2.5 mL of water and applied to Dowex 1 anion-exchange columns (formate form). The inositol phosphates were separated by sequential elution as described.^{18,19} Radioactivity in portions of each fraction was determined by scintillation counting in the gel phase using Insta-Gel II as scintillation fluid. Results were corrected for all loss factors.

Measurement of protein phosphorylation. Protein phosphorylation in response to stimulation of platelets by NaF was measured as ³²P incorporation into proteins after labeling of the platelet metabolic phosphate pool with carrier-free ³²PO₄.^{21,22} ACD-anticoagulated PRP was applied to Sepharose 2B columns, and platelets were eluted with Ca²⁺-free and PO₄³⁻-free Tyrode's solution (136 mmol/L of NaCl, 2.7 mmol/L of KCl, 12 mmol/L of NaHCO₃, 2 mmol/L of MgCl₂, 5.5 mmol/L of glucose pH 6.8) containing BSA (3.5 mg/mL) and apyrase (60 μg/mL). For labeling, gel-filtered platelets (3 × 10⁸/mL) were incubated with ³²PO₄ (0.8 mCi/mL) for 1 hour at 37 °C. Thereafter, platelets were again gel-filtered using Ca²⁺-restored and PO₄³⁻-restored Tyrode's solution without albumin and apyrase for elution. The platelet count was adjusted to ~2 × 10⁸/mL. Samples of 0.9 mL of the final platelet suspension were incubated while being stirred with 0.1 mL of NaF/NaCl-containing reaction mixtures at 37 °C for varying times. The incubation was terminated by addition of 0.1 mL of 3 mol/L of HClO₄. The precipitated proteins were isolated by centrifugation at 10,000 g for 5 minutes and separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) using the Laemmli buffer system.²³ Gels were stained with Coomassie brilliant blue, and the specific areas corresponding to the 40-kd and 20-kd proteins were excised and counted for Cerenkov radiation in a liquid scintillation counter.

Measurement of cytosolic free Ca²⁺ concentrations. Platelets were isolated from citrated PRP by gel filtration on Sepharose 2B using an elution buffer containing 10 mmol/L of HEPES, 145 mmol/L of NaCl, 5 mmol/L of KCl, 0.5 mmol/L of NaH₂PO₄, and 6 mmol/L of glucose pH 7.4. For loading with Quin 2, gel-filtered platelets (~1.5 × 10⁸/mL) were incubated with 10 μmol/L of Quin 2/AM for 1 hour at 37 °C. To remove extraneous dye, platelets were again gel-filtered with the same elution buffer, which contained no added Ca²⁺ or Mg²⁺ in order to prevent disturbance of the fluorescence measurements due to formation of insoluble CaF₂ or MgF₂. The final platelet count was adjusted to ~1 × 10⁸/mL. NaF-induced changes in cytosolic free Ca²⁺ concentrations ([Ca²⁺]_i) were measured as changes in Quin 2 fluorescence intensity after addition of 0.1 vol of NaF/NaCl-containing reaction mixtures in a fluorescence spectrophotometer (Locarte, England). Measurements were made at 37 °C with an excitation wavelength of 339 nm and an emission wavelength of 492 nm. Under these conditions, no autofluorescence of NaF was observed. The fluorescence signal was calibrated in separate samples in the absence of NaF essentially as described.²⁴⁻²⁶ Changes in [Ca²⁺]_i were expressed in percentage of basal [Ca²⁺]_i that was measured in resting platelets prior to addition of NaF.

Measurement of [³H]cAMP. For labeling, PRP anticoagulated with EDTA was incubated with [³H]adenine (15 μCi/mL) for 30 minutes at 20 °C. Labeling was terminated by centrifugation at 800 g for 10 minutes at 20 °C and resuspension of the platelet pellet in an equal amount of citrated autologous plasma. Aliquots of 0.45 mL of the final platelet suspension were incubated with 0.05 mL of NaF/NaCl-containing reaction mixtures at 37 °C for varying times. In some experiments, 10 mmol/L of MIX or 0.05 μmol/L of PGI₂ was added to the platelet suspension prior to or following the

stimulation by NaF as indicated. The incubation was stopped by addition of 0.05 mL of 3 mol/L of trichloroacetic acid containing [^{14}C]cAMP (0.2 $\mu\text{Ci/mL}$) for assessment of recovery. After thorough mixing, the precipitated proteins were removed by centrifugation at 10,000 g for 5 minutes, and total ^3H - and ^{14}C -radioactivity in the supernatant was determined by liquid scintillation counting. cAMP was isolated from the trichloroacetic acid extract by ion-exchange chromatography on Dowex AG 50W-X4 followed by $\text{ZnSO}_4/\text{Ba}(\text{OH})_2$ precipitation of adenine nucleotides other than cAMP as described.^{27,28} The precipitate was spun down by centrifugation at 10,000 g for 5 minutes and ^3H - and ^{14}C -radioactivity in the final supernatant was measured. Results were corrected for spillover and loss factors and expressed as percentage of basal [^3H]adenine incorporation into cAMP that was measured under control conditions (addition of 0.1 vol of 1 mol/L of NaCl). Basal [^3H]adenine incorporation into cAMP ranged between 0.06% and 0.12%.

Measurement of total lactate dehydrogenase (LDH). Total LDH activity was measured spectrophotometrically as described.²⁹ LDH activity was determined in citrated platelet-poor plasma (PPP) either after addition of 0.1 vol of 1 mol/L of NaCl or NaF to PPP or after incubation of PRP with 0.1 vol of 1 mol/L of NaCl or NaF for 10 minutes at 37 °C and subsequent removal of platelets by centrifugation at 10,000 g for 5 minutes. For estimation of the maximal increase in LDH activity caused by lysis of the platelets, digitonin (50 $\mu\text{mol/L}$) was added to separate samples of PRP immediately after addition of NaCl or NaF. These samples were further processed as detailed previously.

RESULTS

Effect of NaF on platelet aggregation and ATP release. NaF caused irreversible aggregation of platelets and secretion of platelet granule contents as measured by ATP release in a strictly dose-related manner (Fig 1). The peak aggregation response was observed at NaF concentrations of ~30 mmol/L. At higher concentrations, the onset of aggregation was more rapid; maximal increase in light transmission was reduced, however, and aggregation was almost entirely inhibited at NaF concentrations >70 mmol/L. Moreover, at these concentrations, platelets became refractory to subsequent stimulation by thrombin, collagen, adenosine 5'-diphosphate (ADP), arachidonic acid, platelet-

activating factor (PAF), and calcium ionophore A23187 added in threshold concentrations 1 minute after addition of NaF (data not shown). Threshold concentrations of these agonists were determined in NaCl-treated control samples. Shape change, reflected by the initial decrease in light transmission, occurred at all concentrations tested. As illustrated in Fig 1B, platelet shape change was delayed and prolonged at low concentrations of NaF whereas it occurred almost instantaneously at high concentrations. Platelet aggregation induced by 30 mmol/L of NaF was not inhibited by apyrase, acetylsalicylic acid, or the PAF antagonist CV-3988,³⁰ in concentrations sufficient to inhibit aggregation by threshold concentrations of ADP, arachidonic acid, and PAF, respectively. In addition, the aggregation response to 30 mmol/L of NaF was not blocked by preincubation of PRP with a combination of high concentrations of apyrase (5 mg/mL), acetylsalicylic acid (0.2 mmol/L), and CV-3988 (20 $\mu\text{mol/L}$) for 3 minutes (data not shown), indicating that the NaF-induced aggregation was independent of ADP release, arachidonic acid metabolism, or endogenously synthesized PAF. The concentration-response curve of NaF-induced ATP release essentially paralleled that of the aggregation response, with the exception that its peak was shifted to 40 mmol/L of NaF and that, at high concentrations of NaF that almost completely inhibited aggregation, there was still a marked release of ATP. ATP release occurred more rapidly with increasing concentrations of NaF.

Time-related and concentration-related effects of NaF on inositol phosphate formation. NaF-induced phospholipid cleavage of platelet membrane phosphoinositides was monitored by measuring the formation of radioactive inositol phosphates in [^3H]inositol-labeled platelets. As demonstrated in time-progress experiments (Fig 2), NaF at low (30 mmol/L) and high (80 mmol/L) concentrations caused a rise in inositol 1-phosphate (IP1) and inositol 1,4-bisphosphate (IP2) levels. The increase in IP2 was detectable after 30 seconds at both concentrations tested and preceded the rise in IP1. The formation of both IP1 and IP2 appeared to be

Fig 1. Effect of NaF on platelet aggregation and ATP release. Citrated platelet-rich plasma (PRP) was exposed to increasing concentrations of NaF in the presence of luciferin/luciferase reagent in a Lumi-Aggregometer as described in the Materials and Methods section. Panel A shows the maximal increase in light transmission (●) reflecting platelet aggregation and the maximal plasma concentrations of adenosine triphosphate (ATP) (○) released from platelets measured during an observation period of 10 minutes. The difference in light transmission between PRP and PPP was set equal to 100%. Points represent means $\pm$ SE of four experiments. Panel B shows representative tracings of platelet aggregation induced by different concentrations of NaF.

Fig 2. Time course of NaF-induced changes in inositol phosphate formation. [^3H]Inositol-labeled platelets were incubated with either 30 mmol/L of NaF + 70 mmol/L of NaCl ($\circ$) or 80 mmol/L of NaF + 20 mmol/L of NaCl ($\bullet$) for varying periods of time. For determination of zero time values ($\blacksquare$), 100 mmol/L of NaCl was added to the samples and the reaction was stopped immediately. Formation of radioactive inositol phosphates was measured as detailed in the Materials and Methods section. Points represent means $\pm$ SE of five experiments. IP1, inositol 1-phosphate; IP2, inositol 1,4-bisphosphate; IP3, inositol 1,4,5-trisphosphate.

delayed at lower concentrations of NaF. This observation was confirmed by the findings of dose-response experiments in which the concentration-dependent differences in inositol phosphate formation were compensated by prolongation of the incubation time from 5 to 10 minutes (Fig 3). A small increase in inositol 1,4,5-trisphosphate (IP3) was measured within 30 seconds of addition of 80 mmol/L of NaF. No clear-cut changes in IP3 formation were detected when platelets were stimulated with lower concentrations of NaF, however, NaCl in a final concentration of 100 mmol/L did not affect inositol phosphate formation (data not shown).

Effect of NaF on protein phosphorylation. Preliminary time-course experiments (data not shown) revealed that the 40-kd protein was maximally phosphorylated within about 4 minutes of addition of 100 mmol/L of NaF. In dose-response experiments (Fig 4), ^{32}P -labeled platelets were therefore incubated with increasing concentrations of NaF for either 1, 4, or 10 minutes. A minor rise in ^{32}P content of the 40-kd protein after incubation for 1 minute was observed only at NaF concentrations of ≥ 40 mmol/L. At these concentrations, 40-kd protein phosphorylation was maximal after 4 minutes, yielding $\sim 350\%$ to 500% of control values, and a marked dephosphorylation was measured on further

Fig 3. Concentration-related and time-related effects of NaF on inositol phosphate formation. [^3H]Inositol-labeled platelets were incubated with different concentrations of NaF as indicated for either 5 (A) or 10 minutes (B); 100 mmol/L of NaCl was added to controls (0 mmol/L of NaF). IP1 ($\bullet$), IP2 ($\circ$), and IP3 ($\blacksquare$) were determined as described in the Materials and Methods section. A representative experiment is shown. Abbreviations as in legend to Fig 2.

prolongation of the incubation time to 10 minutes. In contrast, at low concentrations of NaF, ^{32}P incorporation into the 40-kd protein continued to rise when the incubation time was extended from 4 to 10 minutes, reaching a maximum of $\sim 450\%$ of control values. These data indicate that the rate rather than the maximal degree of 40-kd protein phosphorylation was concentration-dependent. Only minor changes in ^{32}P incorporation into the 20-kd protein were observed (data not shown), which was in accordance with the relatively small rises in $[\text{Ca}^{2+}]_i$ induced by NaF (see below); 20-kd

Fig 4. Concentration-related and time-related effects of NaF on 40-kd protein phosphorylation. ^{32}P -labeled platelets were incubated while being stirred with various concentrations of NaF for either 1 minute ($\bullet$), 4 minutes ($\circ$), or 10 minutes ($\blacktriangle$). Isolated platelet proteins were separated by electrophoresis on 12% sodium dodecyl sulphate-polyacrylamide gels, and radioactivity in specific areas of the gels corresponding to the 40-kd protein was determined as described in the Materials and Methods section; 100 mmol/L of NaCl was added to controls (0 mmol/L of NaF). ^{32}P Radioactivity in the 40-kd protein bands in controls was set equal to 100% and ranged between 440 and 850 cpm. The data shown are representative of two experiments.

Fig 5. Time-course of NaF-induced changes in platelet cAMP levels. [^3H]Adenine-labeled platelets were incubated with either 30 mmol/L of NaF + 70 mmol/L of NaCl (●) or 100 mmol/L of NaF (○) for various periods of time as indicated, and [^3H]cAMP was determined as detailed in the Materials and Methods section. Basal [^3H]adenine incorporation into cAMP was measured after incubation of platelets with 0.1 vol of 1 mol/L of NaCl for 20 seconds and was set equal to 100%. Values are given as means $\pm$ SE of triplicate incubations. The data shown are representative of four experiments.

protein phosphorylation essentially paralleled cytosolic free Ca^{2+} fluxes.

Time-related and concentration-related effects of NaF on cytosolic free Ca^{2+} and platelet cAMP levels. As illustrated in Fig 5, NaF promoted a dose-dependent transient rise in platelet cAMP levels. Net cAMP formation peaked already within 10 to 20 seconds of addition of 100 mmol/L of NaF, whereas the much smaller maximal increment in platelets when stimulated with 30 mmol/L of NaF was observed after 30 seconds. Thus, it is likely that the results of dose-response experiments in which platelets were incubated with different concentrations of NaF for 20 seconds underestimate to a minor extent the effect of low concentrations of NaF on platelet cAMP levels.

The increase in $[\text{Ca}^{2+}]_i$ observed when platelets were stimulated with NaF was preceded by a lag period which in its length was inversely related to the concentration of NaF used. For evaluation of concentration-related effects of NaF on $[\text{Ca}^{2+}]_i$, peak $[\text{Ca}^{2+}]_i$ was calculated from the maximal Quin 2 fluorescence signal observed during 10 minutes following the addition of NaF.

Figure 6 gives an integrated view on the dose-related effects of NaF on peak $[\text{Ca}^{2+}]_i$ and peak cAMP levels. At low concentrations of NaF (<40 mmol/L), net cAMP formation was only little affected, whereas $[\text{Ca}^{2+}]_i$ increased in a dose-dependent manner to maximally 200% to 250% of basal values. In contrast, at concentrations >40 mmol/L, there was a marked depression of NaF-induced Ca^{2+} mobilization that coincided with a dose-dependent exponential increase in peak cAMP levels. Because [^3H]cAMP formation was deter-

Fig 6. Concentration-dependent effects of NaF on platelet peak cAMP levels (●) and cytosolic free Ca^{2+} concentrations (○). [^3H]Adenine-labeled platelets were incubated with increasing concentrations of NaF for 20 seconds, and [^3H]cAMP was determined. Results are expressed in percentage of basal [^3H]adenine incorporation into cAMP and are given as means $\pm$ SE of triplicate incubations (experimental details are described in the Materials and Methods section). The experiment shown is representative of four. $[\text{Ca}^{2+}]_i$ was measured in gel-filtered platelets suspended in low $[\text{Ca}^{2+}]_i$ -containing buffer using the fluorescent Ca^{2+} probe Quin 2. Results reflect maximal $[\text{Ca}^{2+}]_i$ measured during an observation period of 10 minutes after addition of various concentrations of NaF and are expressed in percentage of basal $[\text{Ca}^{2+}]_i$. Points represent means $\pm$ SE of at least three experiments.

mined in PRP and $[\text{Ca}^{2+}]_i$ was measured in platelets suspended in low $[\text{Ca}^{2+}]_i$ -containing buffer, a direct comparison of these dose-response curves may be somewhat artificial. Nevertheless, the data strongly point to an inverse relationship between NaF-induced cAMP formation and Ca^{2+} mobilization.

NaF-induced inhibition of adenylate cyclase. The preceding data show that NaF-treatment of platelets results in a transient rise in cAMP that is followed by a rapid decline to slightly elevated or basal levels (Fig 5). A similar time course was observed in the presence of PGI_2 (Fig 7). Incubation of platelets with 0.05 $\mu\text{mol/L}$ of PGI_2 resulted in a rapid rise in cAMP levels that reached a maximum after 3 minutes and only gradually decreased during the following 10 minutes. Addition of 30 or 100 mmol/L of NaF to platelets that were preincubated with 0.05 $\mu\text{mol/L}$ of PGI_2 for 3 minutes promoted a marked further dose-dependent increase in platelet cAMP levels that peaked after 10 seconds. At both NaF concentrations tested, however, the temporary enhancement of PGI_2 -induced cAMP formation was followed by a rapid decrease in cAMP to clearly below the levels maintained by stimulation with PGI_2 alone. These data were suggestive of either an NaF-induced activation of a cAMP phosphodiesterase or a delayed inhibitory effect of NaF on adenylate cyclase activity. When platelets were preincubated with 10 mmol/L of MIX, a potent cAMP phosphodiesterase inhibitor,³¹ for 4 minutes prior to exposure to either 100 mmol/L of NaCl or 30 mmol/L of NaF and 70 mmol/L of NaCl for an

Fig 7. Effect of NaF on prostacyclin (PGI_2)-stimulated cAMP accumulation. [^3H]Adenine-labeled platelets were incubated with 0.05 $\mu\text{mol/L}$ of PGI_2 for 3 minutes prior to addition of either 100 mmol/L of NaCl ($\square$), 30 mmol/L of NaF + 70 mmol/L of NaCl ($\bullet$), or 100 mmol/L of NaF ($\circ$). At the time points indicated, [^3H]cAMP was determined as described in the Materials and Methods section. Results are expressed in percentage of basal [^3H]adenine incorporation into cAMP and are given as means $\pm$ SE of triplicate incubations. The data shown are representative of three experiments.

additional 4.5 minutes, a slow progressive rise in platelet cAMP levels attributable to cAMP phosphodiesterase inhibition was observed (Fig 8). The slightly larger rise measured on addition of NaF was probably due to minor stimulation of adenylate cyclase. When finally 0.05 $\mu\text{mol/L}$ of PGI_2 was added, cAMP levels progressively increased over the next 10 minutes in the NaCl-treated controls. In the NaF-treated samples, the further increase in cAMP achieved by addition of PGI_2 was strikingly smaller, indicating that NaF indeed exerted a delayed inhibitory effect on adenylate cyclase. Our data, however, do not rule out that NaF, in addition, stimulates a low-affinity cAMP phosphodiesterase.

LDH measurements. Incubation of platelets with either 100 mmol/L of NaCl or 100 mmol/L of NaF did not cause a detectable rise in total LDH activity in citrated plasma, indicating that neither treatment caused measurable lysis of platelets.

DISCUSSION

We showed that NaF at optimal concentrations causes irreversible aggregation of platelets and secretion of granule contents as measured by ATP-release. The aggregation induced by NaF cannot be blocked by a combination of high

Fig 8. Effect of NaF on prostacyclin (PGI_2)-induced stimulation of adenylate cyclase. [^3H]Adenine-labeled platelets were incubated with 10 mmol/L of 3-isobutyl-1-methyl xanthine (MIX) for 4 minutes prior to addition of either 100 mmol/L of NaCl ($\bullet$) or 30 mmol/L of NaF + 70 mmol/L of NaCl ($\circ$). After an additional 4.5 minutes, adenylate cyclase was stimulated by 0.05 $\mu\text{mol/L}$ of PGI_2 . Samples for determination of [^3H]cAMP (described in the Materials and Methods section) were taken at various time points as indicated. Results are expressed in percentage of basal [^3H]adenine incorporation into cAMP and are given as means $\pm$ SE of triplicate incubations. The data shown are representative of three experiments.

concentrations of specific inhibitors that entirely abolishes aggregation by arachidonic acid, ADP, and PAF, respectively. Thus, it can be assumed that NaF exerts its agonistic effects on platelet function through a mechanism that is independent of the formation of cyclooxygenase products or the release of ADP or PAF.

An early event in agonist-induced platelet activation is the phospholipase C-catalyzed hydrolysis of phosphatidylinositol and its phosphorylated derivatives.^{3,4,32} This results in the generation of intermediate breakdown products that function as intracellular messenger molecules, among them IP₃, which mobilizes Ca^{2+} from intracellular storage sites,^{33,34} and diacylglycerol, the endogenous activator of protein kinase C.^{35,36} Stimulation of platelets by NaF increases the formation of inositol phosphates, indicating the activation of a phosphoinositide-specific phospholipase C. NaF-induced phosphoinositide turnover leads to activation of protein kinase C, as demonstrated by phosphorylation of its major substrate in platelets, a 40-kd protein,^{4,37,38} and a rise in cytosolic free Ca^{2+} , which in turn triggers the phosphorylation of a 20-kd protein previously identified as a myosin light chain.³⁹ In this study, we failed to detect any clear-cut changes in IP₃ formation at NaF concentrations that evoked maximal Ca^{2+} mobilization. Because the rise in IP₃ even on

stimulation of platelets by thrombin is only transient and minor as compared with the increase in IP₂ and IP₁,¹⁹ however, it is possible that the assay used is not sensitive enough to detect a slow rise in IP₃ which, in addition, could be outbalanced by its rapid degradation. Therefore, the most likely explanation for the agonistic effects of NaF on platelet function would still be that NaF through activation of phospholipase C initiates an intracellular signal cascade that finally leads to platelet aggregation and release of granule contents. On the other hand, our data do not entirely exclude the existence of a Ca²⁺-mobilizing agent distinct from IP₃ that is formed or activated on NaF stimulation of platelets.

The time lag that precedes the NaF effects related to platelet activation decreases with increasing concentrations of NaF and may thus reflect the time required for NaF to reach its site of action either within the platelet membrane or possibly within the platelet cytosol. Our data herein are consistent with previous studies reporting a delayed mobilization of cytosolic free Ca²⁺ in platelets,¹⁵ neutrophils,⁴⁰ and hepatocytes⁴¹ exposed to NaF.

When the concentration of NaF is raised to >40 mmol/L, a dose-dependent reduction in the maximal amplitude of platelet aggregation is observed, and pretreatment of platelets with 70 to 100 mmol/L of NaF even prevents aggregation in response to stimulation by various other agonists. At these concentrations, NaF induces a dose-dependent transient rise in platelet cAMP, which probably accounts for the concomitant reduction in Ca²⁺ mobilization.⁴²⁻⁴⁴ Inositol phosphate formation and 40-kD protein phosphorylation are not affected by the cAMP transients, suggesting that neither phospholipase C nor protein kinase C action is inhibited by a short-lived increase in cAMP levels. We thus conclude that the observed inhibition of platelet function at high concentrations of NaF is due to the increase in cAMP, which counteracts the mobilization of cytosolic free Ca²⁺ and mainly thereby inhibits aggregation and release reaction. Alternatively, NaF at high concentrations might interfere with the formation or activation of a Ca²⁺-mobilizing messenger distinct from IP₃ or directly stimulate a Ca²⁺ pumping activity, thus reducing the cytosolic free Ca²⁺ concentration.

Platelet shape change is not and ATP release is only partially inhibited even at the highest concentrations of NaF tested, which would confirm the earlier observations that shape change and release reaction can occur with virtually no detectable rise in cytosolic free Ca²⁺ as measured by the fluorescent Ca²⁺ indicator Quin 2.^{26,45}

The rapid reversal of the NaF-stimulated increase in platelet cAMP levels raises the hypothesis that NaF may, in addition, either activate a cAMP phosphodiesterase or exert a delayed inhibitory effect on adenylate cyclase. The latter possibility is confirmed by the observation that NaF-pretreatment of platelets partially inhibits PGI₂-induced cAMP accumulation in the presence of MIX; this experiment, however, does not preclude an additional effect of NaF on a cAMP phosphodiesterase.

Because in platelet membrane preparations NaF has been shown to activate the stimulatory (N_s) as well as the inhibitory (N_i) guanine nucleotide-binding protein involved in the regulation of adenylate cyclase activity,^{12,13} it is possible that the dual effect of NaF on adenylate cyclase in intact platelets mirrors the concentration-dependent, concomitant, or successive activation of both N_s and N_i. In extension of this hypothesis, we further suggest that a NaF-sensitive N protein may also play a role in the activation of phospholipase C. We observed activation of phospholipase C by NaF independent of a rise in cytosolic free Ca²⁺ and despite high cAMP transients. In granulocyte membranes, an N protein is required for the stimulation of phosphoinositide-specific phospholipase C at resting cytosolic free Ca²⁺ concentrations.⁴⁶

In conclusion, we demonstrated that NaF, as a result of simultaneous modulation of phospholipase C and adenylate cyclase activity, has a biphasic, concentration-dependent effect on the function of intact human platelets. The action of NaF may be linked to its known capacity to activate N proteins.

Factor XIIIa Formation Promoted by Complexing of α -Thrombin, Fibrin, and Plasma Factor XIII

By Charles S. Greenberg, Komandoor E. Achyuthan, and John W. Fenton II

Fibrin polymers (des A,B fibrinogen) reduced the concentration of α -thrombin required for 50% activation of plasma factor XIII (a_2b_2 tetramer) by approximately 100-fold. In the presence of fibrin, the amount of γ -thrombin required for activation was not affected. Catalytically inactive *i*-Pr₂P- and D-Phe-Pro-Arg-CH₂- α -thrombin were found to inhibit over 95% of the activation by α -thrombin in the presence of fibrin. Unlike plasma factor XIII, the concentration of α -thrombin required for 50% activation of platelet factor XIII (a_2 dimer) was lower, and the activation was not enhanced by fibrin. However, when the a_2 platelet factor XIII was incubated with purified b-chains, the α - and γ -thrombin concentrations required for activation increased tenfold

and reached levels similar to those required for activation of the plasma factor XIII. When fibrin was present, the α -thrombin concentrations needed for activation of the a_2b_2 complexes were reduced, and the presence of fibrin had no effect on γ -thrombin cleavage of the a_2b_2 complexes. Therefore, the b-chains must inhibit a-chain cleavage by α -thrombin in the absence of fibrin. These results imply that the formation of a cocomplex involving α -thrombin, fibrin, and plasma factor XIII causes some conformational change in plasma factor XIII such that the b-chains no longer inhibit cleavage of the a-chains.

© 1987 by Grune & Stratton, Inc.

PLASMA FACTOR XIII (a_2b_2) is composed of two "a" and two "b" polypeptide chains that form a tetramer in circulating blood. Upon cleavage of factor XIII, the activation peptides are released and form an inactive intermediate, factor XIII' (a_2b_2).¹ In the presence of Ca²⁺ and fibrin(ogen), factor XIII' undergoes a conformational change that results in the dissociation of b-chains and the formation of factor XIIIa.² In this process, the presence of fibrin(ogen) reduces the Ca²⁺ concentration required for b-chain dissociation³ and also enhances thrombin-catalyzed release of the activation peptides from the a-chains of purified plasma factor XIII.⁴

In our studies examining the factors affecting the activation process, we found that α -thrombin would cause a 43-fold more rapid release of fibrinopeptide A from fibrinogen than activation of plasma factor XIII. Previous studies had found that a temporal relationship existed between fibrin polymerization and factor XIII activation and that inhibition of fibrin polymerization delayed the activation event without inhibiting fibrinopeptide A release.⁵ In addition, the polymerization of des-A-fibrinogen and des-A,B-fibrinogen accelerated the rate of thrombin cleavage of plasma factor XIII in afibrinogenemic plasma,⁶ and inhibition of fibrin polymerization by Gly-Pro-Arg-Pro prevented fibrin polymerization and significantly reduced the rate of plasma factor XIII cleavage by thrombin.^{5,6} Furthermore, the plasma factor XIII was found to bind specifically to polymerized fibrinogen and fibrin fibers, and the binding was not affected by other plasma proteins or divalent cations.⁷

Unlike plasma factor XIII, platelet factor XIII is composed of two a-chains alone yet binds like its plasma counterpart to fibrin(ogen), which suggests that the a_2 -subunit may mediate binding.^{7,8} Since fibrin(ogen) has been found to selectively bind α -thrombin,⁹⁻¹³ we have proposed that the formation of a cocomplex involving thrombin, fibrin, and plasma factor XIII promotes the formation of factor XIIIa.⁶ Unlike α -thrombin, γ -thrombin lacks clotting activity and binds very weakly to fibrin(ogen)^{10,11} yet retains its catalytic activity and cleaves factor XIII.¹⁴ When the catalytic serine and histidine residues are covalently conjugated with *i*-Pr₂P-F or D-Phe-Pro-Arg-CH₂-Cl, α -thrombin becomes irreversibly inactivated.^{15,16} These α -thrombin conjugates cannot cleave plasma factor XIII or clot fibrinogen solutions, yet they can bind to fibrin(ogen) and compete for α -

thrombin binding sites.¹⁰⁻¹² In the present study, we used modified thrombin to explore the mechanisms of fibrin-mediated enhancement of plasma factor XIII activation. The binding of both α -thrombin and plasma factor XIII to fibrin was found to be required for the rapid activation of plasma factor XIII.

MATERIALS AND METHODS

Factor XIII-deficient plasma was purchased from George King Biomedical (Overland Park, KS) and adsorbed with 15 mg/mL of bentonite (Sigma Chemical Co, St Louis) for 30 minutes at 22 °C.⁶ Human plasma and platelet factor XIII were purified from fresh, frozen plasma and stored at -70 °C.^{17,18} Fibrinogen and des-A,B-fibrinogen were prepared as previously described,⁶ and D-Phe-Pro-Arg-CH₂-Cl, *i*-Pr₂P-F, anti-factor XIII a-chain and anti-factor XIII b-chain antibodies were purchased from Calbiochem-Behring Corp (La Jolla, CA).

Thrombin preparations. Human α -thrombin was purified from fraction III paste and stored frozen at -70 °C in 0.75 mol/L NaCl, pH 6.0. This preparation contained a final protein concentration of 69.7 μ mol/L, an active site titration of 68.2 μ mol/L, and fibrinogen clotting activity of 3,100 US National Institutes of Health (NIH) U/mg.¹⁹ γ -thrombin was prepared by passing purified α -thrombin through a trypsin-agarose column²⁰ and stored as noted before (52 μ mol/L protein, 24.8 μ mol/L active site titration, and 0.36 NIH U/mg activity). Inactivated *i*-Pr₂P- α -thrombin was prepared by repeated additions of the fluoride reagent to α -thrombin until the clotting activity declined to <2%. This was followed by extensive

dialysis against 0.75 mol/L NaCl at 4 °C,⁹ and the enzyme was stored frozen (52 μ mol/L protein, <0.5 μ mol/L active site titration, and 0.37 NIH U/mg activity). Affinity-labeled D-Phe-Pro-Arg-CH₂- α -thrombin was made by incubating equimolar amounts of the chloromethyl ketone reagent and α -thrombin for one hour followed by dialysis to remove unreacted reagent. Protein concentrations were calculated from absorbance at 280 nm by using an extinction coefficient of 1.83 mg/mL/cm and a molecular weight of 36,500 for α -thrombin.¹⁹ All concentrations of reagents used in the study were based upon the absolute protein concentrations rather than the active site concentrations.

Measurement of α - and γ -thrombin cleavage of plasma and platelet factor XIII in the presence and absence of des-A,B-fibrinogen. α - or γ -thrombin at 0.01 to 1,000 nmol/L was incubated with 6 nmol/L platelet factor XIII or 9 nmol/L plasma factor XIII for five minutes at 37 °C in the presence or absence of 620 nmol/L des-A,B-fibrinogen in Tris-buffered saline (0.13 mol/L NaCl at pH 7.4 and 0.02 mol/L Tris-HCl (TBS), and 5 mmol/L CaCl₂). Thrombin was inhibited by a 100-fold molar excess of D-Phe-Pro-Arg-CH₂-Cl, and factor XIIIa was assayed after stabilization in a buffer containing glycerol at 4 °C.²¹ Preliminary experiments demonstrated that the presence of D-Phe-Pro-Arg-CH₂-Cl did not interfere with the factor XIIIa assay. Less than 5% of the factor XIII preparation expressed activity in the absence of α -thrombin, and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis demonstrated over 87% cleavage of the a-chains by thrombin in the factor XIII preparations.⁵

Factor XIIIa assay. Plasma and platelet factor XIIIa formation was quantitated using the [³H]-putrescine incorporation assay.²¹ Factor XIIIa activity was expressed as nanomoles of putrescine incorporated into casein in 60 minutes at 37 °C, where this activity correlated with thrombin cleavage of the a-chains.⁵ Factor XIIIa activity was expressed as the percentage of total factor XIIIa determined after incubating samples with 5 mmol/L CaCl₂ and 190 nmol/L α -thrombin at 37 °C for 15 minutes.

Effect of *i*-Pr₂P- and D-Phe-Pro-Arg-CH₂-thrombin on α -thrombin cleavage of plasma factor XIII in the presence or absence of fibrinogen. Concentrations of either *i*-Pr₂P-thrombin or D-Phe-Pro-Arg-CH₂-thrombin ranging from 9 to 90 nmol/L were incubated at 22 °C for five minutes in TBS containing 9 nmol/L plasma factor XIII and the presence or absence of 620 nmol/L fibrinogen. These reaction mixtures were subsequently incubated for five minutes at 37 °C with 9 nmol/L α -thrombin followed by the addition of 1 mmol/L D-Phe-Pro-Arg-CH₂-Cl. Factor XIIIa activity was measured by the [³H]-putrescine incorporation assay. Samples of the reaction mixtures that contained fibrinogen were further ultrafiltered through an Amicon ultrafiltration cell using an X M 100A membrane (Amicon Corp, Danvers, MA) to determine whether the effect of the modified thrombins was reversible.

Effect of plasma factor XIII b-chains on α -thrombin cleavage of factor XIII a-chains. Plasma containing only factor XIII b-chains was prepared by bentonite adsorption of factor XIII-deficient plasma. The adsorbed plasma was electrophoresed through agarose gels containing either anti-a-chain or anti-b-chain antisera to demonstrate the absence of a-chains and the presence of b-chains.²² Equal volumes of 0.24 μ mol/L platelet factor XIII (a₂) and bentonite-adsorbed factor XIII-deficient plasma were incubated for 15 minutes at 22 °C. Following incubation, the samples were diluted to 20% vol/vol with TBS and incubated for five minutes at 37 °C with 0.01 nmol/L to 10 nmol/L α -thrombin and in the presence or absence of 0.62 μ mol/L des A,B fibrinogen. In another set of reaction mixtures, purified factor XIII b-chains²³ at 3.6 nmol/L were incubated with 2.4 nmol/L platelet factor XIII a-chains in TBS for 15 minutes at 22 °C. To these, either 0.01 to 10 nmol/L of α -thrombin or 0.1 to 100 nmol/L γ -thrombin was added, and the

samples were incubated for 15 minutes at 37 °C in the presence or absence of 620 nmol/L des A,B fibrinogen. The reactions were stopped by the addition of D-Phe-Pro-Arg-CH₂-Cl to 1 μ mol/L, and the level of factor XIIIa formation was determined by the [³H]-putrescine incorporation assay.

Formation of a₂b₂ complex (plasma factor XIII) by binding of b-chains to a-chains. Platelet factor XIII was radioiodinated with Na¹²⁵I using lactoperoxidase to a level of 5,620 cpm/ng.⁸ The radiolabeled a-chains were incubated at 6 nmol/L with 80 nmol/L purified b-chains for 15 minutes at 22 °C. Complexes formed in the reaction mixture as well as radiolabeled plasma factor XIII (2,680 cpm/ng) were electrophoresed through discontinuous PAGE.² The gels were stained and dried, and autoradiography was performed to identify the location of radiolabeled factor XIII a-chains bound to purified b-chains. Autoradiograms were scanned using a GS-300 scanning densitometer (Hoefer, San Francisco) to quantitate the amount of ¹²⁵I-labeled a-chains that had complexed with b-chains.

Measurement of fibrin polymerization. Purified fibrinogen at 2 mg/mL was incubated with 10 nmol/L of α -thrombin in TBS containing 5 mmol/L CaCl₂. The level of fibrin polymerization was measured as previously described,²¹ and the rate of polymerization was calculated as a function of the maximum slope of the polymerization curve.

RESULTS

Fibrin polymers generated from des A,B fibrinogen reduced the level of α -thrombin required for 50% activation of plasma factor XIII by approximately 100-fold. In contrast, the level of γ -thrombin required for 50% activation had slightly increased in the presence of fibrin (Fig 1). On a functional enzyme basis, the α -thrombin and γ -thrombin preparations were 97.8% active (μ mol/L active site/ μ mol/L protein $\times$ 100) and 47.7% active, respectively. Therefore, α -thrombin exhibited an approximate 15-fold increase over γ -thrombin in its ability to activate the plasma factor XIII in the absence of fibrin and an increase greater than two orders of magnitude over γ -thrombin in the presence of fibrin. In control experiments, 1000 nmol/L γ -thrombin could not

Fig 1. Plasma factor XIII activation by α - or γ -thrombin in the presence or absence of fibrin polymers. Factor XIII was activated and assayed as described in the text; it was incubated with α -thrombin (○—○) or γ -thrombin (□—□) alone (open symbols) or plus des A,B fibrinogen (solid symbols).

inhibit activation of the plasma factor by 1.0 nmol/L α -thrombin in either the presence or absence of fibrin.

Since the fibrin used in the aforementioned experiments was generated by diluting ten- to 20-fold des A,B fibrinogen in 1 mol/L NaBr, the high salt concentrations could potentially interfere with thrombin binding to fibrin(ogen). To address this issue, experiments were conducted with fibrin generated in situ from fibrinogen reacted with α -thrombin. We found that a tenfold molar excess of inactivated *i*-Pr₂P- or D-Phe-Pro-Arg-CH₂- α -thrombin inhibited over 95% of the activation of plasma factor XIII by α -thrombin in the presence of fibrin(ogen) (Fig 2), but neither appreciably inhibited factor XIII activation in the absence of fibrin(ogen).

The highest concentrations of catalytically inactivated thrombins did not interfere with fibrin formation by α -thrombin in the fibrinogen-containing solutions. However, when these solutions were subsequently ultrafiltered through membranes with a 100,000-dalton cutoff, they regained their ability to promote α -thrombin activation of factor XIII. Dialyzing the modified-thrombin solutions did not interfere with their ability to competitively inhibit α -thrombin cleavage of the plasma factor XIII with fibrin. In addition, when 1.8 μ mol/L α -thrombin was added to 9 nmol/L plasma factor XIII with 90 nmol/L *i*-Pr₂P- α -thrombin, additional factor XIIIa was formed.

Unlike the plasma factor, platelet factor XIII required approximately tenfold less α -thrombin for 50% activation, and the activity was not enhanced by the presence of fibrin (Fig 3). γ -Thrombin was at least an order of magnitude less active relative to α -thrombin and was essentially unaffected by the presence of fibrin. However, when platelet factor XIII was incubated with either afibrinogenemic plasma containing b-chains or isolated b-chains from plasma factor XIII, the α -thrombin concentration required to activate the a_2b_2 complexes increased by approximately tenfold in the absence

Fig 2. Inhibition of α -thrombin activation of plasma factor XIII with catalytically inactivated thrombins in the presence of fibrin. Des A,B fibrinogen and plasma factor XIII were incubated with increasing concentrations of either *i*-Pr₂P- (○—○) or D-Phe-Pro-Arg-CH₂- α -thrombin (□—□) for 15 minutes prior to assaying factor XIIIa activity, as described in the text. Similar reactions were performed in the absence of fibrin (closed symbols).

Fig 3. Platelet factor XIII activation by α - or γ -thrombin in the presence or absence of fibrin polymers. See Fig 1: α -thrombin alone (○—○) or α -thrombin plus des A,B fibrinogen (●—●); γ -thrombin alone (□—□) or γ -thrombin plus des A,B fibrinogen (■—■).

of fibrin and was decreased by approximately tenfold in the presence of fibrin (Fig 4). The presence of b-chains inhibited γ -thrombin cleavage of platelet factor XIII (Fig 5), and the presence of fibrin was not found to enhance γ -thrombin cleavage of the a_2b_2 complexes (data not shown).

In additional experiments, platelet factor XIII a-chains were radiolabeled with ¹²⁵I and incubated with isolated factor XIII b-chains. When electrophoresed according to Lorand et al.,² 86% the a-chains migrated as the a_2b_2 complex, which comigrated with plasma factor XIII (data not shown).

DISCUSSION

Fibrin generated from the polymerization of des A,B fibrinogen clearly amplified the α -thrombin activation of plasma factor XIII by approximately 100-fold. This form of the human enzyme exhibits high fibrinogen-clotting activity as well as all other thrombin-associated characteristics.^{19,20} The autoproteolytic or tryptic degradative form of thrombin, γ -thrombin, lacks clotting activity but retains its substrate-binding and certain other enzymic traits.²⁰ Although this form has been shown to activate plasma factor XIII,¹⁴ such activation was not found to be enhanced by the presence of fibrin. This suggests that a fibrin(ogen) recognition site necessary for clotting must be involved in the enhancement phenomenon.

Like α -thrombin, catalytically inactivated forms bind tightly to nonpolymerized fibrin immobilized in agarose and are eluted by similar salt concentrations. Both of the modified forms compete for α -thrombin binding sites and were found to inhibit 95% of the activation of plasma factor XIII by the native enzyme. In contrast, the binding of γ -thrombin to nonpolymerized fibrin is very weak¹¹ and was not found to compete with α -thrombin in the activation of plasma factor XIII. Since the *i*-Pr₂P-group is an obstructive moiety conjugated to the catalytic serine residue and the D-Phe-Pro-Arg-CH₂-group fills the fibrinopeptide groove adjacent to

Fig 4. Platelet factor XIII incubated with the plasma factor XIII b-chains and activated with α -thrombin in the presence or absence of fibrin. Platelet factor XIII activated by α -thrombin in the absence of fibrin or b-chain ($\triangle$ — $\triangle$). In addition, plasma containing b-chains with (●—●) or without (○—○) fibrin polymers was incubated with platelet factor XIII and activated with α -thrombin. Isolated b-chains were also incubated with platelet factor XIII and activated by thrombin with (■—■) or without (□—□) fibrin polymers.

the catalytic site,^{15,16} an exosite independent of the catalytic site and adjacent regions must be required for α -thrombin complexing with fibrin(ogen).

The presence of fibrin was not found to enhance the activation of platelet factor XIII by α -thrombin. However, when the platelet factor, which has an a_2 -chain structure, was incubated with b-chains from the plasma factor XIII, an a_2b_2 complex was formed. The activation of this hybrid complex by α -thrombin was enhanced by approximately 20-fold in the presence of fibrin. Although the isolated b-chains cannot complex with fibrin(ogen) alone, yet the a_2 dimers can,^{7,8} the in vitro complexing of a-chains with b-chains clearly inhibited α - and γ -thrombin cleavage of the a-chain when fibrin was absent. Thus, our data strongly suggest that activation of plasma factor XIII proceeds via the formation of cocomplex involving α -thrombin, the a_2b_2 complex, and fibrin.

Earlier investigations suggested that plasma factor XIII b-chains inhibit α -thrombin cleavage of the a-chains.²³ Our data support these findings since approximately tenfold more α -thrombin or γ -thrombin was required to activate plasma factor XIII or the hybrid (a_2b_2) complexes relative to platelet factor XIII (a_2). Our data further demonstrate a previously unrecognized change in the interaction between the a- and b-chains during the clotting event. We have found that the b-chains inhibit cleavage of the a-chains by α - and γ -thrombins in the absence of fibrin. However, in the presence of fibrin, the b-chains no longer inhibit α -thrombin cleavage

Fig 5. Effect of b-chains on Platelet factor XIII activation by γ -thrombin. Platelet factor XIII was activated by γ -thrombin in the presence (○—○) or absence (●—●) of b-chains. Platelet factor XIII was activated and assayed as described in the text.

of the a-chains. Since the γ -thrombin concentration required to cleave the a-chains was not affected by the presence of fibrin, the binding of thrombin to fibrin must be required for thrombin activation of plasma factor XIII. We propose that the b-chains bind to the a-chains of the a_2b_2 complex, which protects them from thrombin binding in circulating blood. However, in the presence of fibrin, a binding of the a_2b_2 complex to the fibrin polymer leads to a conformational change in the a- and b-chain geometry, which promotes formation of the activation complex.

Preliminary experiments have indicated that non-cross-linked fibrin protofibrils promote α -thrombin activation of plasma factor XIII,²⁴ whereas other data show that soluble, cross-linked fibrin does not.²⁵ Thus, the activation complex appears to occur transiently during fibrin polymerization. This is also true in the active entrapment process whereby α -thrombin becomes incorporated into fibrin clots.¹⁰

The mechanism by which fibrin modifies the interaction between a- and b-chains to promote thrombin cleavage does not appear to involve a requisite dissociation of the b-chains from the complex since des A,B fibrinogen promotes thrombin cleavage of plasma factor XIII in the presence of EDTA under conditions whereby the b-chains do not dissociate from the a-chains.⁶ The b-chain may actively promote a conformational change in the a-chain, or the a-chains may undergo a conformational change that rearranges the position of the b-chains within the complex.

Durability of Responses to Interferon Alfa-2b in Advanced Hairy Cell Leukemia

By Mark J. Ratain, Harvey M. Golomb, Ronald G. Bardawil, James W. Vardiman, Carol A. Westbrook, Lynne S. Kaminer, Barry C. Lembersky, Mitchell A. Bitter, and Karen Daly

Previous studies have demonstrated that significant hematologic improvement occurs in the majority of patients with hairy cell leukemia (HCL) treated with partially purified or recombinant interferon (IFN). Fifty-three patients received IFN alfa-2b for at least 3 months in a dose of 2×10^6 U/m² subcutaneously thrice weekly. Of the 49 patients evaluable for response (at least 6 months of IFN therapy), there were ten complete responses and 29 partial responses for a total response rate of 80%. The peripheral blood counts and bone marrow continued to improve over the course of a full year of therapy. IFN was well tolerated, with no patients discontinuing therapy because of toxicity. Transient myelosuppression occurred in most patients during the first 1 to 2 months of therapy, occasionally precipitating a trans-

fusion requirement. After IFN treatment was discontinued, there was a marked decrease in normal marrow elements and a relative increase in marrow hairy cells. This was associated with a transient increase in normal elements in the peripheral blood. Only one of 24 patients followed after receiving IFN for a median of 8.5 months (range, 3 to 16 months) has required further therapy. We conclude that low-dose IFN alfa-2b is highly effective in advanced HCL; responding patients should be treated for at least 1 year. The decision to initiate a second course of IFN therapy should be based primarily on peripheral blood counts and the clinical status of the patient rather than on the bone marrow.

© 1987 by Grune & Stratton, Inc.

HAIRY CELL LEUKEMIA (HCL) was first described by Bouroncle et al in 1958.¹ Splenectomy has long been considered the initial treatment of choice,² but patients with advanced disease postsplenectomy have historically been difficult to treat because of persistent neutropenia following even low-dose chemotherapy.³

Quesada et al⁴ first demonstrated that a partially purified interferon product was highly effective in advanced HCL, and Ratain et al⁵ showed that interferon itself was the active molecule using the recombinant drug. These initial results with recombinant interferon have subsequently been confirmed in a multiinstitution study of 64 patients,⁶ and the results of several large series have recently been reviewed.⁷ The objectives of this analysis from a single institution are to extend and update our experience with interferon alfa-2b (IFN) in advanced HCL and to determine the duration of response to IFN by careful assessment of peripheral blood and bone marrow changes following discontinuation of therapy.

MATERIALS AND METHODS

Patient eligibility. Requirements for inclusion in the study were as follows: (1) pathologically confirmed diagnosis of HCL on the basis of a recent (within 1 month) bone core biopsy; (2) significant

anemia (hemoglobin, <12 g/dL), thrombocytopenia (platelets, <100,000 cells/ μ L), neutropenia (neutrophils, <1,000 cells/ μ L), and/or leukemia (white blood count, >10,000 cells/ μ L with more than 50% hairy cells); (3) prior splenectomy, unless refused by the patient; (4) normal hepatic and renal function; (5) past the nadir of toxicity of any previous therapy (chemotherapy and/or radiotherapy), preferably no treatment in the previous 4 weeks; and (6) informed consent in accordance with procedures defined by the Department of Health and Human Service.

Study design. IFN (Intron A, Schering Corp, Kenilworth, NJ) was supplied as lyophilized powder (10×10^6 and 50×10^6 U/vial) and reconstituted with sterile water. The initial dose of IFN was 2×10^6 U/m² self-administered subcutaneously three times weekly. Dose escalation up to 10×10^6 U/m² was allowed for nonresponders but used in only two patients. Five of the first six patients were initially treated with 10×10^6 U/m², but it was deescalated when the lower dose was shown to be active. Patients were admitted to the hospital for the first two doses to facilitate teaching of IFN reconstitution and administration and to observe for unexpected toxicity.

Patients were seen monthly at the University of Chicago. Treatment was continued for 12 months in responding patients. Patients completing 12 months of IFN therapy after January 1985 were entered in a randomized study comparing an additional 6 months of IFN therapy to observation. Patients were stratified by response (at the time of randomization), as defined in the next section.

While receiving IFN, a complete blood count (and differential) was obtained weekly until patients showed objective evidence of response, then it was done monthly. A chemistry panel was obtained monthly. Bone marrow biopsy specimens were obtained at least every 3 months. Since the neutrophil alkaline phosphatase score (NAP) has previously been shown to be elevated in HCL,⁸ we also determined the NAP every 3 months. After discontinuation of IFN therapy, a complete blood count was obtained monthly. A chemistry panel, NAP, and bone marrow biopsy specimen were obtained every 3 months for the first year of follow-up and then every 6 months.

Response criteria. Patients were considered eligible for response after 6 months of therapy. Although responses occur within 1 to 2 months of starting IFN treatment, prior studies have demonstrated that the absolute neutrophil count (ANC) and hemoglobin level may improve continuously over the first 6 months of therapy.⁶ The response criteria used in this analysis are similar to those reported previously.⁴⁻⁷

A complete response (CR) was defined as (a) normalization of peripheral blood counts (hemoglobin, >12 g/dL; platelets, >100,000 cells/ μ L; and ANC, >1,500 cells/ μ L) and (2) less than 5% hairy cells in the bone marrow biopsy specimen. (Patients with

focal clumping of hairy cells in the bone marrow were not considered to have a CR).

A partial response (PR) designated normalization of peripheral blood counts but not meeting the pathological criteria for a CR.

A minor response (MR) was defined as normalization of at least one peripheral blood count initially abnormal but not meeting the criteria for a PR. Leukemic patients with only a decrease in WBC to the normal range were also considered to have an MR.

No response (NR) met none of the aforementioned criteria.

Bone marrow studies. All bone marrow biopsy specimens were reviewed initially by a hematopathologist (J.W.V. or M.A.B.). The bone marrow biopsy specimens on all patients not receiving IFN for at least 3 months were rereviewed by two of the authors (R.G.B. and J.W.V.) and analyzed as previously described.⁹ This included differential counts of 2,000 to 5,000 cells on the histological sections.

The volume of each marrow subpopulation was quantitated based on the estimated cellularity and the differential as follows: volume of subpopulation = percent cellularity $\times$ percentage of subpopulation/10,000. This analysis is similar to the stereological analysis of Flandrin et al¹⁰ and our prior use of the hairy cell index (HCI)¹¹: percent cellularity $\times$ percentage of hairy cells/10,000. We have also quantitated the non-hairy cell index (NHCI) at various time points; it was defined as (the percent cellularity/100) - HCI. Occasional bone marrows were severely hypocellular (<10% cellularity), especially after IFN therapy was stopped. Frequently the peripheral blood counts obtained simultaneously suggested that these biopsy specimens were not considered representative of the patient's bone marrow, and thus nine of 56 marrows (19%) obtained after IFN therapy was stopped were excluded from further analysis.

Statistical analysis. Paired parametric (Student's *t*) and nonparametric (Wilcoxon) tests were used to analyze the changes in peripheral blood counts, NAP, and bone marrow subpopulations during and after IFN therapy. Patients with RBC or platelet transfusion requirements were considered to have a hemoglobin or platelet count of zero for the purpose of this analysis. In general, the Wilcoxon test was used to avoid assuming a normal distribution of data. However, the paired *t* test was used to assess the changes in peripheral blood counts after completion of IFN therapy because of the greater power of this test.

RESULTS

Patient characteristics. We have entered 59 patients in our phase II trial from October 12, 1983, to March 15, 1986. Thirty-three of these patients have been reported previously, with follow-up through February 1985.^{5,6,12} Fifty-three of the 59 patients have completed at least 3 months of therapy (as of March, 15, 1986) and are the subject of this paper (Table 1). Four of the remaining six patients have been recently entered in the study. One patient with refractory thrombocytopenia died of an intracerebral hemorrhage during the first week of therapy,⁵ and one patient with advanced HCL and severe emphysema (requiring continuous oxygen) died of pneumonia during the first month of therapy.

As noted in Table 1, four patients did not have a prior splenectomy. One patient refused a splenectomy, consistent with the stated eligibility criteria. In the other three non-splenectomized patients, the decision to use IFN was made on clinical grounds because all three patients had small spleens and a high percentage of hairy cells in the marrow and would not be expected to have a durable response to splenectomy.¹¹

All but one patient had one or more cytopenias or were in

the leukemic phase of the disease. Forty patients (76%) were anemic (hemoglobin, <12 g/dL), and 19 patients (36%) were receiving RBC transfusions. Twenty-seven patients (51%) were thrombocytopenic (platelets, <100,000 cells/ μ L), and 12 patients (23%) required platelet transfusions. Most patients (70%) were neutropenic, and three patients had less than 100 neutrophils/ μ L prior to IFN therapy. Fourteen patients (26%) were in the leukemic phase of the disease. Five of our patients also had symptomatic bony lesions, including one patient with normal blood counts.

Responses. Of the 53 patients described earlier, 50 patients have completed at least 6 months of therapy. (The other three patients are still receiving IFN). The patient with normal blood counts at study entry, but symptomatic bony lesions, is not evaluable for hematologic response. Major responses were seen in 80% of the 49 evaluable patients, with ten CRs (20%) and 29 PRs (59%). An additional nine patients (19%) had MRs. Only one evaluable patient has not responded to therapy.

Two patients had IFN dose escalations from 2×10^6 U/m² to 10×10^6 U/m² after 4 to 5 months of therapy. The IFN dose in the single nonresponder was increased after 4 months of IFN. There was no improvement over the next 2 months, and IFN therapy was discontinued. No further therapy was administered (except for transfusions) over the next 16 months. The other patient in whom the IFN dose was escalated had not responded despite 5 months of IFN, although his ANC had increased from 144 to 620 cells/ μ L. He showed further improvement over the next month but was not considered a PR until 1 month after stopping IFN treatment (at the end of a full year).

Only one patient had a worsening of his blood counts while receiving IFN. The patient initially responded (MR) to IFN and was randomized to an additional 6 months of IFN at the end of 1 year. After 14 months of therapy, his blood counts deteriorated, and IFN therapy was discontinued.

Changes in peripheral and bone marrow parameters during IFN therapy. As shown in Table 2, the median hemoglobin level improved continuously over the first 12 months of IFN therapy, increasing from 10.6 g/dL to 14.7 g/dL. The platelet count improved dramatically over the first 3 months, but there was only minimal improvement with subsequent therapy. The ANC also improved rapidly, but

there continued to be significant improvement over the first year.

Most of the bone marrow changes also occurred during the first 9 months. The bone marrow cellularity significantly decreased over the first 3 months (Table 2) and decreased further from months 6 to 9, prior to increasing slightly from months 9 to 12. The relative percentage of hairy cells in the bone marrow appeared to decrease continuously over the first year, with a further decrease ($P = .08$) from months 12 to 18 (nine patients only). The HCI significantly decreased over the first 9 months of IFN, with little subsequent change. The NHCI increased over the first 3 months but changed little over the next 6 months. However, there was significant improvement in the NHCI from months 9 to 12.

Table 2 also illustrates the dramatic changes that occur in the NAP with IFN therapy. The median NAP decreased from 204 to 31 over the first 9 months of IFN, but there was no further change over the next 3 to 9 months.

Toxicity. The nonhematologic toxicity that occurred in out HCL patients was very similar to that described in prior reports.^{6,13} Constitutional symptoms occurred in all patients and consisted of a "flu-like syndrome," fatigue, and anorexia. Gastrointestinal symptoms were common and included nausea/vomiting (17%) and diarrhea (32%). Neurological toxicity included both peripheral neuropathies (32%) and CNS dysfunction (21%). The latter usually consisted of subtle memory loss or depression, except for one patient with Cancer and Leukemia Group B (CALGB) grade 3 confusion that required a temporary withdrawal of IFN therapy. Other

common toxicities included injection site inflammation (45%), dry skin or seborrheic dermatitis (58%), alopecia (17%), and chemical hepatitis (74%). The latter was usually manifested as an elevated SGOT or SGPT level (79%), but the alkaline phosphatase value was occasionally elevated (28%). All toxicity was CALGB grade 1 or 2 (except for the one patient noted before), and no patient discontinued therapy due to toxicity, although one patient with severe fatigue refused randomization.

Transient myelosuppression was a very common event during the initial 1 to 2 months of therapy. Changes in the ANC were of the greatest magnitude (Table 3), but transfusions were occasionally required because of worsening anemia (two patients) and thrombocytopenia (two patients) due to IFN therapy.

Follow-up after discontinuation of IFN therapy. Of the 53 patients described in this report, 34 patients have completed at least 12 months of IFN therapy. Twenty-six patients were entered in the randomized study, 13 patients in each arm (12 v 18 months of IFN therapy). Eight patients were not randomized, mainly due to the fact that the randomized study was not opened until February 1985. Twenty-four patients have not been receiving IFN for at least 3 months and were studied further, as described in Materials and Methods. Sixteen patients discontinued IFN therapy after 12 months, seven patients completed 18 months of IFN treatment (6 months after randomization), and one patient discontinued IFN therapy after 6 months due to no response. This subset of 24 patients is fairly representative of the entire group of 53 patients: median age of 47 years, 88% male, and 75% complete or partial responders. The median time without IFN therapy is 8.5 months, with a maximum of 16 months. There was a significant increase during the first post-IFN month in the platelet count ($P = .004$) and ANC ($P = .05$), which reversed over the next 2 months (Fig 1). There was a significant increase in the hemoglobin level ($P = .01$) from months 1 to 3 after stopping IFN therapy, which reversed over the subsequent 3 months. In addition, the NAP

increased over the first 3 months in all 16 patients studied, with the median NAP increasing from 40 to 92 ($P < .001$). There were no other significant changes in any of the peripheral blood parameters over the first year of follow-up.

There were also definite changes in the bone marrow over the first 3 months after stopping IFN therapy (Fig 2). Sixteen patients had evaluable marrows both prior to stopping IFN treatment and 3 months later. (Five patients had severely hypocellular marrows at 3 months only, one patient had a severely hypocellular marrow both prior to stopping IFN therapy and 3 months later, one patient had a poorly prepared marrow at 3 months, and one patient did not have a marrow prior to stopping IFN treatment.) Over the first 3 post-IFN months there was a decrease (not statistically significant) in the median cellularity (42.5% v 35%, $P > .05$) and an increase in the relative proportion of hairy cells (21.5% v 47.5%, $P < .001$). The decrease in total cellularity appears to be due to a decrease in the myeloid (17.6% v 8.3%, $P < .001$) and erythroid (18.3% v 11.7%, $P < .01$) volumes, but there was no significant decrease in the myeloid:erythroid ratio (0.9 v 0.6, $P > .05$). An example of these morphological changes is presented in Fig 3. There were no statistically significant changes over the subsequent 9 months, although there was an overall increase in the leukemic volume.

A small subset of six patients did have a major increase in HCL over the first 9 months after IFN treatment (Fig 4). Although the follow-up has been short, only one patient has required further therapy after relapsing with a high WBC (23,000 cells/ μ L) after 6 months of observation. His initial response status was MR, and he has responded to his second course of IFN over the first month of treatment.

DISCUSSION

This paper confirms our preliminary report of the effectiveness of IFN in advanced HCL.⁵ IFN, when administered at a dose of 2×10^6 U/m² three times weekly, leads to normalization of blood counts and improvement in the bone

Fig 3. Bone marrow changes in a representative patient during and after IFN therapy. Prior to IFN therapy (A), the bone marrow was 95% cellular with 83% hairy cells. After 18 months of IFN therapy (B), the marrow was 75% cellular with less than 5% hairy cells, and the patient was considered to have a CR. However, there was myeloid hypoplasia with a myeloid:erythroid ratio of 0.7. Three months after stopping IFN therapy (C), the cellularity was 50% with 25% hairy cells. Note the further decrease in the myeloid:erythroid ratio to 0.5.

Fig 4. Six patients with an increased HCL (>0.4) after stopping IFN therapy. Only one patient (○) has required further IFN therapy. Note also that one patient (●) had an increase in the HCL from month 0 to 3, which decreased over the next 6 months.

marrow in 80% of patients treated for at least 6 months. The therapy is well tolerated, with no patients discontinuing IFN treatment due to toxicity. Comparable results have been reported with the similar drug, interferon alfa-2a.^{10,14,15} Changes in the peripheral blood counts and bone marrow occur rapidly, with significant improvement over the first 3 months, especially in the platelet count. There continues to be improvement over the first year in both the peripheral blood counts and bone marrow.

One of the primary purposes of this analysis was to define the extent and course of hematologic changes occurring after discontinuing IFN therapy. We demonstrate that responses to IFN are quite durable, with only one of 24 patients followed for a median of 8.5 months who required further therapy. In addition, there were no significant changes in peripheral blood counts over the first post-IFN year, except for a rebound increase in all three cell lines demonstrated at months 1 to 3. There did appear to be significant changes in the bone marrow after stopping IFN therapy that were characterized by a decrease in normal myeloid and erythroid elements. In addition, there was a trend towards an increasing HCL over the first year after stopping IFN treatment, which has not yet reached statistical significance.

Study of the changes in the bone marrow after stopping IFN therapy may provide insight into the mechanisms of interferon-induced myelosuppression. The major hematologic toxicity of interferons is leukopenia, with a decrease of 40% to 60% in the WBC during the first week of treatment but with no further decrease with continued therapy.¹³ Ernstoff and Kirkwood¹⁶ have previously analyzed bone marrows in patients with nonhematologic malignancies who received IFN. There was a trend toward an increase in normal precursors but no maturation arrest. Our data demonstrate that there is a marked decrease in normal myeloid and erythroid marrow elements after stopping IFN therapy

simultaneous with a rebound increase in the peripheral blood count. This suggests that IFN directly or indirectly inhibits the release of normal marrow elements and that this process is reversed when IFN therapy is discontinued—a hypothesis previously proposed by Ernstoff and Kirkwood.¹⁶

We also demonstrate in this paper that IFN leads to normalization of another hematologic parameter that is abnormal in patients with HCL, the NAP. A previous report by Golomb et al⁸ noted an increased NAP in 15 of 17 patients studied. The median pretreatment NAP in our patients was markedly elevated at 204, which decreased to a nadir of 31 by month 9 but increased after stopping IFN therapy. A high NAP score may reflect a decrease in marrow myeloid elements, since these were the two major changes after discontinuing IFN treatment. A more detailed analysis of the relationship of NAP to peripheral blood counts and bone marrow subpopulations is in progress.

We continue to emphasize that IFN therapy is only palliative because discernible hairy cells remain in the bone marrow of virtually all patients. In addition, the bone marrow remains abnormal, even in complete responders, with increased reticulin and myeloid hypoplasia.⁹

We propose that patients with progressive HCL following splenectomy be treated with IFN for at least 6 months. Responding patients should be treated for 1 year. Information regarding longer periods of treatment will be available after analysis of a multiinstitution study randomizing patients to 12 v 18 months of IFN therapy. Practicing physicians must be aware of the transient myelosuppression that occurs in the first 1 to 2 months of therapy, possibly precipitating the need for RBC and/or platelet transfusions. Following the discontinuation of IFN therapy patients should be monitored with complete blood counts every 1 to 3 months. Although the bone marrow may change significantly after IFN treatment is stopped, it should not necessarily be used as a guide to reinstitution of IFN therapy.

We cannot yet recommend IFN as initial therapy to patients in lieu of splenectomy, although Quesada and co-workers recently report the attainment of a CR in five of seven nonsplenectomized patients.¹⁷ In addition, the eventual role of IFN in the therapy of HCL is uncertain because of the high complete response rates (23% to 65%) reported from preliminary studies of the adenosine deaminase inhibitor pentostatin.¹⁸⁻²² If possible, patients with HCL should continue to be entered in clinical trials.

The Secretory Pathway of Bovine Platelets

By James G. White

Human platelets contain tortuous channels in their cytoplasm, the surface-connected or open canalicular system (OCS), that communicate directly with the surrounding medium through openings on the surface membrane. Some workers have suggested that the OCS serves as the egress route for products secreted during the release reaction. Others have proposed alternate secretory pathways. Since bovine platelets lack the OCS found in human cells, the present study has examined the secretory mechanism of these cells to see whether it can shed light on the mystery of human platelet secretion. Bovine platelet granules, in contrast to human granules, are located more peripherally in resting cells (often in contact with the plasma membrane), most do not move centrally following thrombin stimulation as do human platelet granules, and many fuse directly with the external plasma membrane without any intermediate channel. The lack of peripheral location of human granules, their central rather than peripheral move-

ment during secretion, and the presence of extensive channels are all consistent with the larger importance of the secretory channel to human platelets. Thus, though studies of bovine secretion do show that platelets can secrete their granules by direct fusion of granule and surface membranes, other differences from human platelets emphasize that this pathway, although important to bovine platelet secretion, is less important in human platelets. Studies of bovine platelets also show that the OCS is more dynamic than might have been considered from human studies and can form rapidly in response to stimulation. Such newly formed channels are used as a conduit for secretion of granule contents. The finding emphasizes the importance of channels for granule secretion in platelets generally and puts a new perspective on the ability of these cells to form channels rapidly in response to stimulation.

HUMAN PLATELETS are secretory cells.¹ Three different types of secretory organelles including alpha granules, dense bodies, and lysosomes are randomly dispersed in the cytoplasm of resting platelets.²⁻⁴ Following exposure to aggregating agents, platelets lose their discoid form, become irregular with multiple pseudopods, and concentrate organelles in cell centers.⁵ The physical alterations are intimately associated with the discharge of chemical substances to the surrounding medium.⁶

The mechanism by which products stored in the secretory granules of human platelets are released to the exterior without simultaneous loss of cytoplasmic constituents has been the subject of considerable interest.⁷⁻¹² Investigations using electron-dense tracers revealed the existence of a surface-connected open canalicular system (OCS) in resting human cells.¹³ After activation, storage organelles appeared to fuse with channels of the OCS, which then served as conduits for the release of secretory products.¹²⁻¹⁵ Other workers using different techniques proposed an alternate pathway for secretion.¹⁶ They suggested that centrally concentrated organelles fuse to form a closed sac that then migrates to the platelet surface, attaches to the membrane, and extrudes its products to the outside.

A recent study of bovine platelets has suggested the existence of a model for examining the two different concepts of platelet secretion.¹⁷ Zucker-Franklin et al¹⁷ have shown that bovine cells lack the OCS found in human cells. Therefore, cattle platelets must have some mechanism other than channels of the OCS for discharging products from secretory granules to the outside.¹⁸ The present study has searched for the secretory pathway in bovine platelets with the aid of freeze-fracture and electron-dense tracers.

MATERIALS AND METHODS

Blood for the present study was obtained from healthy adult cattle housed under direct supervision of the School of Veterinary Sciences at the University of Minnesota. Samples aspirated from the external jugular vein were mixed immediately with citrate-citric acid-dextrose (CCD) (93 mmol/L trisodium citrate, 70 mmol/L citric acid, 140 mmol/L dextrose, pH 6.5) in a ratio of nine parts blood to one part anticoagulant.¹⁹ Blood was sedimented at room temperature under a force of 200 g for 20 minutes. Platelet-rich plasma (C-PRP) above the buffy coat was aspirated and transferred to separate tubes. After determining the platelet count, the samples of C-PRP in each tube were combined with equal volumes of the CCD anticoagulant and centrifuged to pellets. The plasma was replaced with Hanks' balanced salt solution (HBSS) containing 0.1 mmol/L EDTA. After 30 minutes at 37 °C, the pellets were resuspended in HBSS with or without EDTA to produce a platelet count of 500,000/ μ L and returned to the 37 °C water bath.²⁰ Samples were fixed for study in the electron microscope at 30 seconds and 1, 3, and 5 minutes after exposure to thrombin at concentrations of 1, 3, and 5 U/mL. Each thrombin concentration and time of exposure was examined in four to seven experiments.

Fixation was accomplished by combining the sample at the appropriate time with an equal volume of 0.1% glutaraldehyde in White's saline (a 10% solution of a 1:1 mixture of (1) 2.4 mmol/L NaCl, 0.1 mmol/L KCH₃, 46 mmol/L MgSO₄, and 64 mmol/L Ca (NO₃)₂ · 4H₂O and (2) 0.13 mol/L NaHCO₃, 8.4 mmol/L NaH₂PO₄, and 0.1 g/L of phenol red, pH 7.4). After 15 minutes the samples were centrifuged to pellets and the supernatant fixative removed and replaced with 3% glutaraldehyde in the same buffer.¹⁹ The samples resuspended in the second aldehyde fixative were maintained at 4 °C for 30 minutes and then sedimented to pellets. The supernatant was removed and replaced with either 1% osmic

acid in Zetterquist's buffer or 1% osmic acid in distilled water containing 1.5% potassium ferrocyanide for one hour at 4 °C.²¹

Tannic acid has been used in our previous studies as an electron-dense stain for the OCS of human platelets.^{22,23} In the present study the method was modified from the procedure reported by Somlyo²⁴ to stain the secretory pathway of bovine platelets. Bovine cells washed and resuspended as described before and exposed to thrombin in the presence or absence of EDTA were fixed through our usual sequence of 0.1% glutaraldehyde in White's saline followed by sedimentation to a pellet, removal of the supernatant, and replacement with 3% glutaraldehyde in the same buffer for two hours at 4 °C. After completion of initial fixation steps, the pellets were washed three times and stored overnight in 0.1 mmol/L cacodylate buffer, pH 7.2. The buffer was decanted the following day and replaced with 4% tannic acid in 0.1 mmol/L cacodylate buffer, pH 7.2, for four hours at room temperature. The supernatant was decanted, the pellets washed in cacodylate buffer, and the samples postfixed in 2% osmic acid alone or combined with 1.5% potassium ferrocyanide for two hours at 4 °C.

All samples were dehydrated in a graded series of alcohols and embedded in Epon 812. Thin sections cut from the plastic blocks on an ultramicrotome were examined unstained or after staining with uranyl acetate and lead citrate to enhance the contrast. All examinations were made in a Phillips 301 electron microscope.

Some of the aldehyde-fixed control and activated platelet samples from each experiment were combined with glycerol, frozen in liquid nitrogen, and freeze-fractured under high vacuum.²⁵ Carbon platinum replicas prepared from exposed surfaces of the fractured platelet pellets were cleaned in detergent and examined in the transmission electron microscope.

RESULTS

Resting Bovine Platelets

The fine structure of bovine platelets was described previously by Myers et al¹⁸ and by Zucker-Franklin and her colleagues.¹⁷ Bovine platelets are similar to human cells in many respects. Like platelets of humans, cattle platelets are discoid in form, and their lentiform appearance is supported by a circumferential microtubule (Figs 1 and 2). Bovine platelets contain the granules, dense bodies, and microchondria that are also found in human cells.

There are, however, significant differences between human and bovine platelets. Cattle cells are slightly smaller, contain fewer dense bodies, and their cytoplasm is dominated by granules two to three times larger than those in human platelets.^{17,18} Many of the large granules are spindle shaped and often appear to contact the inside of the surface membrane (Fig 2). An extensive network of tortuous channels communicating with the cell surface and referred to as the OCS in human platelets^{23,26} was not found in bovine cells (Figs 3 and 4). This confirmed the work of others showing that cationized ferritin, an electron-dense tracer, easily entered the channel system of human platelets but did not appear in bovine platelet cytoplasm.¹⁷ Replicas of freeze-fractured bovine platelets also failed to reveal the typical pits formed by channels of the OCS communicating with the surface of platelets from humans (Fig 3).

Thin sections of resting platelets prepared by our usual fixation procedures in the present study also failed to reveal the well-defined system of channels evident in platelets from

humans (Figs 1 and 2). Bovine platelets stained with tannic acid lacked an OCS, and replicas of freeze-fractured cattle platelets contained only rare dimples or pits comparable to the openings of the OCS on the surface membrane of human cells until after stimulation by thrombin (Figs 3 to 6). However, small protrusions about 0.2 μ m in diameter and devoid of intramembranous particles were frequently present on the P face of freeze-fractured resting bovine cells (Fig 3). Fractures through the membrane into the cytoplasm often revealed contact between membranes of the large granules and the undersurface of the cell wall at sites resembling the protrusions or indentations seen on the P face (Fig 4).

Elements of a second system of channels, the dense tubular system (DTS), were fully developed in bovine platelets. However, membrane complexes formed by the interaction of canaliculi from the OCS and DTS were absent (Figs 1 and 2).²² The presence of the platelet-specific peroxidase²⁶ localized to the DTS channels of human platelets confirmed the presence of a DTS in bovine platelets. Thus cattle cells contain the DTS but are deficient in the specialized membrane complexes found in human cells and in platelets from other species.

Thrombin-Stimulated Bovine Platelets

Aggregates. Thin sections of aggregated bovine platelets bore a superficial resemblance to human platelet thrombi. Shape change was evident, and the groups of cells were closely molded to each other as in hemostatic plugs. Dense spots resembling the contracted masses of actomyosin present in thrombin-stimulated human cells were present in many aggregated bovine platelets. However, the central concentration of organelles and enclosure within constricted rings of microtubules and microfilaments, regularly present in activated human platelets,⁵ were rarely evident in bovine platelets. Instead, the granules remained dispersed near the cell periphery. Tannic acid staining of the bovine platelet aggregates revealed electron-dense tracer outlining the spaces between aggregated platelets (Figs 7 and 8). In some cells the tannic acid-osmium product appeared in channel-like structures penetrating into the cytoplasm of the clumped platelets close to the dense spots of actomyosin. Some granules were also stained by tannic acid-osmium, which indicated they were connected to the cell wall or channels reaching the platelet surfaces.

Activated platelets. Thin sections of thrombin-stimulated but not aggregated bovine platelets revealed additional differences in their response compared with their human counterpart (Figs 9 to 20). Spikelike pseudopods extending from shape-changed bovine platelets were thinner and straighter than those formed on activated human platelets. Occasional microtubules are evident in human platelet pseudopods, but most surface projections lack the polymer. Almost every pseudopod extending from bovine platelets contained one or several microtubules interspersed with microfilaments. Microtubules were also present in the cytoplasm of activated bovine platelets (Fig 9). However, instead of being organized in constricted rings around centrally concentrated organelles, the tubules were irregularly dispersed in bundles or loose arrangements. The granules in

Fig 1. Resting bovine platelet. A circumferential microtubule (MT) coiled just under the surface membrane supports the lentiform appearance of the unstimulated cell. Granules (G), occasional mitochondria (M) and a few dense bodies (DB) together with glycogen (Gly) particles are randomly dispersed in the cytoplasm. The resting cell does not appear to contain channels of the open canalicular OCS or dense tubular systems (DTS). (Original magnification $\times 24,000$.) Fig 2. Cross section of discoid cattle platelet. Granules are significantly larger than those in human platelets. They often appear to be in close association ($\uparrow$) or contact with the platelet membrane. (Original magnification $\times 28,000$.) Fig 3. Replica of freeze-fractured bovine platelet. The surface membrane of a discoid cell has been split by the procedure, thereby revealing the outside of the inner layer, or "P" face. Indentations representing sites of continuity between channels of the open canalicular and the surface membrane in human cells are rarely seen in replicas of resting bovine platelets. Dimples ($\uparrow$) or protrusions free of the intramembranous particles covering the rest of the exposed surface are evident on most of the replicas. They may represent sites of contact between granules in the cytoplasm and the inner surface of the cell membrane. (Original magnification $\times 22,000$.) Fig 4. Replica of discoid bovine platelet. Granules (G) in the cytoplasm are in close proximity to depressions in the surface membrane ($\uparrow$) at several points. (Original magnification $\times 28,000$.) Fig 5. Replica of washed bovine platelet exposed to thrombin (3 U/mL, five minutes) in the presence of EDTA. The "P" face contains several indentations ($\uparrow$) similar, if not identical, to the openings of the OCS on replicas of resting human platelets. (Original magnification $\times 25,000$.) Fig 6. Thrombin-activated bovine platelet (1 U/mL, three minutes). Shape change is under way in this cell, but the granules remain peripherally oriented. One organelle (G) has caused the surface membrane to protrude. This may precede extrusion of organelle contents. A small channel ($\uparrow$) is also apparent close to the cell membrane in this cell. (Original magnification $\times 28,000$.)

most platelets were peripherally oriented near the cell membrane rather than concentrated in cell centers.

Although tannic acid failed to stain channels of the OCS or granules in resting bovine platelets, it did so in thrombin-activated cells. Tannic acid appeared to react selectively with

some product in platelet granules, which resulted in a heavy deposit of osmium black (Figs 7 to 12). The electron-dense stain appeared to reach granules through connections between the organelles and the cell surface. The mechanism for development of the openings permitting penetration of

Fig 7. Thrombin-aggregated platelets stained during fixation with tannic acid. Osmic acid deposited as an electron-dense stain by tannic acid coats the cell surface, fills channels penetrating into the cells, and has entered some granules (G) similar in size to unstained organelles. Two of them are in direct continuity with the cell surface through stain-filled channels (C). (Original magnification $\times 17,000$.) Fig 8. Thrombin-aggregated bovine platelets. The preparation is the same as that shown in Fig 7. Tannic acid coats the surface of clumped platelets and fills a channel (C) penetrating into one of the cells. One granule (G) is in direct continuity with the channel, and another adjacent to it is unstained. (Original magnification $\times 28,000$.) Fig 9. Thrombin-activated platelet (1 U/mL, three minutes). Little evidence of shape change is apparent in this cell. Microtubules are still evident at the platelet periphery and adjacent pseudopods. One granule (1) stained by tannic acid appears unconnected to the cell surface, another organelle (2) is very close to it, and a third (3) is open to the surrounding medium. Serial sections of this cell (not shown) reveal that organelles 1 and 2 are also directly connected to the platelet surface. (Original magnification $\times 34,000$.) Fig 10. Thrombin-activated platelets (5 U/mL, one minute). The microtubules (MT) in this cell are in three separate groups. One granule (1) is filled with stain and appears unconnected to the cell surface. However, it must be connected above or below the plane of section to the surface membrane in order to take up tannic acid. Another granule (2) is connected to the cell surface, and its contents appear to be in the process of extrusion. (Original magnification $\times 30,000$.) Fig 11. Thrombin-activated platelet (5 U/mL, one minute). Every pseudopod ($\uparrow$) extending from this platelet or adjacent cells contains microtubules. A granule filled with tannic acid-stained material appears to be in the process of discharge from the platelet. (Original magnification $\times 30,000$.) Fig 12. Thrombin-activated platelet. This cell appears to have reacted maximally to thrombin stimulation. All of the granules appear to have fused with the cell surface and discharged their contents to the exterior. Tannic acid-stained material most likely represents granule contents fixed in situ during extrusion. The dense spot remaining in the cell center is a contracted gel (CG) of actomyosin. Microtubules fill adjacent pseudopods ($\uparrow$). (Original magnification $\times 24,000$.)

Fig 13. Thrombin-activated platelet (1 U/mL, five minutes). The cell contains small and large unstained granules (G) and a dense body in its cytoplasm. A small granule (†) stained with tannic acid is in direct continuity with a fragile-appearing channel (C) connected to the surface membrane. (Original magnification $\times 28,000$.) Fig 14. Thrombin-activated platelet (3 U/mL, five minutes). Dense bodies (DB) and unstained small and large granules fill the cell cytoplasm. A large granule heavily stained by tannic acid is in direct continuity with a channel (C) that undergoes branching. A channel burrows deeper into the platelet cytoplasm, and the other is connected to the cell surface. (Original magnification $\times 28,000$.) Fig 15. Thrombin-activated platelet (5 U/mL, one minute). Several channels (C) or empty granules have scalloped the cell membrane. Fine canaliculi (†) stained by tannic acid extend from the surface deeper into the cytoplasm. One of them connects to a stain-filled granule (G). (Original magnification $\times 28,000$.) Fig 16. Thrombin-activated platelet (5 U/mL, one minute). The cell in this example is irregular with many pseudopods. A granule communicates with the cell membrane on one side of the cell and discharges its contents to the exterior. A channel (C) from deep in the cytoplasm communicates with the surface on the other side. Tannic acid-stained material fills the channel and has been fixed in the process of extrusion from the cell. (Original magnification $\times 28,000$.) Figs 17 and 18. Serial sections of a thrombin-activated platelet. The cell has at least two sites (†) on the surface where tannic acid-stained granule material is in the process of discharge. Two of the tannic acid-stained granules (G) appear to communicate with a channel at the edge of the contracted gel (CG) of actomyosin. A small fragment of a channel (C) filled with tannic acid is buried in the contractile gel in Fig 17 and extends to the cell surface in Fig 18. (Original magnifications $\times 26,000$, Fig 17; $\times 26,000$, Fig 18.)

tannic acid into granules was not clear. However, it must be related to the action of thrombin because connections were not evident in control platelets. The discharge of stained granule contents from thrombin-activated platelets appeared to follow two routes. Most of the granules close to the surface fused with the membrane and secreted directly to the outside medium (Figs 9 to 12). Some examples suggest that granule

products are actively extruded (Figs 10 to 12). Internal contraction leading to the formation of dense spots of contractile gel in thrombin-activated bovine platelets may provide the force for expulsion (Fig 12).

In addition to demonstrating the interaction between granules and the surface membrane in thrombin-activated bovine platelets, tannic acid staining also revealed the devel-

opment of a primitive channel system in activated cells (Figs 13 to 20). The suggestion that channels were newly developed came from observations made on replicas of freeze-fractured platelets. Apertures of the OCS onto the surface membrane of resting and activated human platelets were rarely seen on discoid bovine cells (Fig 3). They were regularly present, however, following exposure of bovine platelets to thrombin (Fig 5). In thin sections of tannic acid-stained bovine platelets, electron-dense product penetrated into fragile channels extending for variable distances into the cytoplasm. Communication between stain-filled channels and granules was easily identified. The channels appeared fragile and lacked the tortuosity and extensive distribution of the OCS in human platelets (Fig 20). Channels were also apparent in replicas of thrombin-stimulated bovine platelets (Figs 6 and 21 to 24). Some branching was noted in replicas, but, in general, the channels were very simple structures.

DISCUSSION

The present investigation has used ultrastructural techniques to search for the secretory pathway in bovine platelets. Cattle cells resemble human platelets closely.^{17,18} Resting platelets from both species have a characteristic discoid shape supported by a circumferential microtubule. The cytoplasm of human and bovine platelets is filled with secretory organelles including dense bodies and alpha granules. Mitochondria and glycogen particles are common in both cells. There are significant differences, however.^{17,18} Bovine platelets are slightly smaller than human cells and more elliptical in form. Dense bodies are less frequent, and the granules are two to three times larger than comparable organelles in human platelets. Granules in cattle platelets often appear to impinge on the surface membrane, whereas this close relationship does not occur in cells from humans.^{14,15}

The major difference between human and bovine cells lies in the membrane systems. An extensive system of channels communicating with the surface membrane and with each other is a characteristic feature of human platelets.^{23,27-29} Zucker-Franklin and her colleagues used an electron-dense tracer, cationized ferritin, and freeze-fracture to demonstrate that bovine platelets lack the surface-connected OCS.¹⁷ Examination of tannic acid-stained platelets and replicas of freeze-etched cells in this study confirmed the absence of a definitive OCS in resting cells from cattle.

The findings suggested that the bovine platelet could serve as a useful model to resolve conflicting concepts regarding the mechanism of platelet secretion. A search for the secretory pathway of activated human platelets had shown that granules fuse with channels of the OCS and are extruded from the cell through these conduits during platelet shape change and internal contraction.^{5,12,13} Other workers reached a different conclusion. Ginsberg et al¹⁶ used immunocytochemistry and electron microscopy to follow secretion in human cells. Centrally concentrated organelles in stimulated platelets fused together to form closed sacs. The sacs of secretory products migrated to the platelet surface, attached

to the membrane, and extruded their contents to the outside.

Since bovine platelets lack the OCS, the concept of secretion in which granules fuse with channels and use the canaliculi for discharge of products did not seem reasonable for cattle cells. Some variation of the hypothesis proposed by Ginsberg and colleagues¹⁶ would seem more tenable. However, the movement of granules toward platelet centers that precedes their intimate association and possible fusion into closed sacs occurs infrequently in bovine platelets.^{17,18}

In the present study thrombin-induced aggregation and activation of bovine cells caused shape change, pseudopod formation, and the development of stickiness, responses closely resembling those of human cells. The internal reaction of cattle platelets, however, was quite different. Central movement of randomly dispersed organelles and their inclusion within tight-fitting rings of microtubules and microfilaments, a regular feature of stimulated human cells,^{5,14,15} occurred rarely in bovine platelets. Instead the microtubule coil appeared to remain peripherally located or fractured during shape change, which resulted in random bundles in the cytoplasm and one to several polymers in each spikelike pseudopod. Granules remained dispersed and close to the inside surface of the cell membrane in thrombin-activated and -aggregated bovine platelets.

Examination of freeze-fractured bovine platelets after exposure to thrombin revealed a marked change from resting cells. Dimples indicating sites of communication between channels of the OCS and the surface were virtually absent from discoid platelets.¹⁷ However, pinpoint depressions, slightly smaller than the openings of the OCS on human platelets, were present on nearly every activated bovine platelet. Short invaginations resembling channels communicating with the surface membrane were present in the cytoplasm of freeze-fractured bovine platelets prepared after exposure to thrombin.

Tannic acid staining of thrombin-aggregated and -activated platelets also revealed dramatic changes from the appearance of resting bovine platelets. Electron-dense stain was deposited in many organelles with the size and shape of granules in activated cells. Some of these were in direct continuity with the irregular platelet surface. Other stained organelles were connected to the cell wall and to each other by narrow channels filled with electron-dense material. In many examples the stain appeared to catch granule products fixed during the process of extrusion from thrombin-stimulated bovine platelets.

The close relationship between the large granules and the surface membrane of bovine platelets would seem to obviate the need for OCS channels found in platelets from humans, pigs, rats, whales, horses, rabbits, and other species. It is surprising, therefore, that bovine platelets either have a few elements of OCS invisible in resting cells or develop them during shape change and internal contraction. Electron-dense stain entered channels communicating with the surface in activated platelets. The channels were narrow, compared with elements of the OCS in human cells, and usually short and unbranched. Some, however, extended far into platelet cytoplasm to form a direct connection to stain-filled

Fig 19. Thrombin-activated platelet (5 U/mL, five minutes). A fully transformed platelet is evident in this illustration. Shape change and contraction of actomyosin gel into a dense spot are advanced. At least two channels contain tannic acid-stained residue, which suggests that they are granules or carry granule products to the surface. (Original magnification $\times 25,000$.) Fig 20. Thrombin-activated human platelet (3 U/mL, three minutes). This cell has been exposed to the same conditions as bovine cells in the present study. A channel of the OCS in continuity with the surface membrane is dilated by tannic acid-stained material. The tortuous channels are connected directly to at least two granules (G), which are also stained by tannic acid. The constricted microtubule (MT) coils are cut in cross section in this example. (Original magnification $\times 23,000$.) Fig 21. Replica of thrombin-activated bovine platelet (3 U/mL, one minute). A fine channel ($\uparrow$) extends from the surface of the stimulated cell deep into the cytoplasm. (Original magnification $\times 28,000$.) Fig 22. Replica of thrombin-activated platelet (3 U/mL, one minute). Two short channels ($\uparrow$) are evidently extending inward from the surface membrane of the activated cell. (Original magnification $\times 30,000$.) Fig 23. Replica of thrombin-activated platelet (3 U/mL, one minute). Two small channels ($\uparrow$) appear to connect granules to the cell surface on the left. On the right, a channel (C) with two openings on the surface may provide a pathway for secretion of some granule products. (Original magnification $\times 28,000$.) Fig 24. Replica of thrombin-activated platelet. One edge of this cell has three openings ($\uparrow$) into a single channel of the OCS, which extends deeper into the cytoplasm close to a granule (G). (Original magnification $\times 30,000$.)

granules. It is possible that the channels developed in activated platelets were the result of infoldings or creases in the membrane or a collapse of granule walls following secretion of their contents. However, except for the extensive distribution of the OCS in human cells and the tortuosity and interconnection of the canaliculi, the appearance of the channels and relationship to granules and the cell membrane in bovine platelets were quite similar.

Thus, the difference in the mechanism of secretion in

bovine compared with human cells is not as great as it might at first seem. Bovine platelets do not have a well-defined OCS. As a result, they use the surface membrane as the primary route for discharge of products from secretory granules. Human platelets have an extensive system of internalized surface membrane formed into channels of the OCS. It is used as the primary route of secretion in human cells. Bovine platelets can develop primitive canaliculi following activation, and granule products may leave the cell

through these conduits. Yet it uses the cell surface as a preferential route for exocytosis. The basis for the species variations in platelet structure that result in different preferred routes for secretion of granule products remains unknown.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Dr Janine Breton-Gorius, CHU Henri Mordor, 94010 Creteil, France, who localized the peroxidase activity in the DTS of bovine platelets.

Expression of the Human Monocyte Membrane Antigen gp55 by Murine Fibroblasts After DNA-Mediated Gene Transfer

By Richard A. Ashmun, Stephen C. Peiper, Matthew B. Rebutisch, and A. Thomas Look

Human DNA sequences that contain the gene encoding gp55, a cell surface glycoprotein expressed exclusively on mature human monocytes and monocytic leukemia cells, were isolated in a mouse genetic background. DNA from mature human monocytes was cotransfected with DNA from a molecularly cloned feline sarcoma virus containing the *v-fms* oncogene into NIH-3T3 cells. Transformed mouse fibroblasts that expressed gp55, based on their reactivity with the MY4, B44.1, or LeuM3 monoclonal antibodies, were selected by fluorescence-activated cell sorting. Regardless of which antibody was used for selection, equivalent binding of all three antibodies was observed for positive transformants. Secondary and tertiary mouse cell transformants were obtained after additional rounds of transfection and cell sorting with the use of DNA from primary and then secondary transformants. Southern blot analysis of the cellular DNA from two inde-

pendently derived tertiary subclones revealed a limited complement of human sequences, thus indicating that the gene encoding gp55 is included in fewer than 50 kilobases of human DNA. Independently derived tertiary subclones displayed concordant patterns of reactivity with 13 monocyte-specific monoclonal antibodies, thus indicating that each recognized an epitope on the product (gp55) of a single human gene. The 55-kilodalton cell surface polypeptide was specifically immunoprecipitated with a representative monoclonal antibody, 26if, from lysates of enzymatically radioiodinated peripheral blood monocytes and tertiary transformants. We conclude that gp55 is highly immunogenic and that a large number of independently derived monoclonal antibodies specific for human monocytes react with epitopes on this one molecule.

MANY MONOCLONAL ANTIBODIES recognize epitopes on the surface of mature cells of the monocyte-macrophage lineage¹ and therefore have proved valuable for studying normal mononuclear phagocytes and their malignant counterparts. With few exceptions, the functions of cell surface antigens recognized by these reagents are unknown, but it is reasonable to speculate that such molecules participate in key cellular activities mediated by monocytes such as antigen processing or cell-mediated cytotoxicity.

One of the monocyte-specific monoclonal antibodies, MY4, precipitates a 55-kilodalton (kd) cell surface glycoprotein (gp55) that is present on monocytes, macrophages, and cells from patients with acute monocytic or myelomonocytic leukemia.²⁻⁴ At least two other monoclonal antibodies including Mo2⁵⁻⁷ and AML-2-23⁸⁻¹¹ display similar patterns of reactivity and immunoprecipitate proteins with similar apparent molecular weights. None of these antibodies reacts with lymphocytes, lymphoid leukemia cells, platelets, or erythrocytes. The antigen recognized by AML-2-23 was shown to be a glycoprotein secreted by cultured human

monocytes and by HL-60 cells induced to differentiate along the monocyte lineage, thus suggesting that it may represent an as-yet-uncharacterized monokine.⁹

We recently used DNA-mediated gene transfer and cell-sorting techniques to isolate and molecularly clone the gene encoding a myeloid cell surface glycoprotein, gp150.¹¹⁻¹³ Mouse NIH-3T3 cells were cotransfected with high-molecular weight human cellular DNA and DNA from cloned feline sarcoma virus containing the *v-fms* oncogene. The *v-fms*-transformed cells that expressed gp150 were selected by fluorescence-activated cell sorting of transformed cell populations stained with a monoclonal antibody specific for the antigen. Antigen-expressing primary transformants isolated in this way typically contained approximately 1,500 kilobases (kb) of human DNA.¹⁴ Successive rounds of cotransfection and cell sorting permitted the isolation of transformants that contained limited human DNA sequences, including those that encoded gp150.

Capitalizing on these methods, we have now isolated transformed mouse cell populations that express gp55 and display concordant reactivities with each of 13 distinct monoclonal antibodies. Independently derived tertiary subclones shown to express gp55 contained a limited subset of human DNA sequences, which indicated that the epitopes recognized by our panel of antibodies were restricted to a product of a single human gene.

MATERIALS AND METHODS

Isolation of peripheral blood leukocyte fractions enriched for monocytes, lymphocytes, and granulocytes. Heparinized peripheral blood was obtained by venipuncture from normal adult volunteers with their informed consent. Mononuclear cell fractions were selected after centrifugation in Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) as described by others.^{15,16} To separate adherent from nonadherent cells, the mononuclear fraction was washed once in Hanks' balanced salt solution (HBSS), resuspended in RPMI 1640 supplemented with 5% fetal calf serum (FCS), and incubated at 37 °C for two hours in plastic tissue culture flasks. Adherent cells were removed from the flask by scraping after incubation for five minutes at 37 °C in 3 mL of 10 µg/mL buffered

trypsin (GIBCO, Grand Island, NY). Nonadherent cell fractions typically contained >90% lymphocytes, with the remainder consisting of monocytes as determined by microscopic examination of Cytospin slide preparations. Adherent cell fractions included 50% to 90% monocytes and contaminating lymphocytes.

Erythrocytes and granulocytes in the Ficoll-Hypaque pellet were resuspended in an equal volume of 0.4% Dextran T-500 (Sigma Chemical Co, St Louis) in HBSS and allowed to sediment for one hour on ice at unit gravity. The granulocyte-rich supernatant was withdrawn and washed twice in hypotonic lysis buffer consisting of 10 mmol/L KHCO₃ (pH 7.4), 155 mmol/L NH₄Cl, and 0.1 mmol/L EDTA to lyse residual erythrocytes. The remaining cells, typically >90% granulocytes as determined by morphological analysis of cytopsin preparations, were resuspended in RPMI 1640 medium with 5% FCS.

Transfection of high-molecular weight DNA. DNA from the cloned McDonough strain of feline sarcoma virus containing the *v-fms* gene¹⁷ was mixed with 5 µg of sheared cellular DNA (ten passages through a 25-gauge needle) and cotransfected into NIH-3T3 cells after precipitation with calcium phosphate as previously described.¹¹⁻¹³ Foci of transformed cells in multiple flasks were counted after ten days, allowed to overgrow the contact-inhibited untransformed NIH-3T3 cells, removed with trypsin, and pooled into groups for fluorescence-activated cell sorting. Control plates of NIH-3T3 cells were transfected with NIH-3T3 DNA alone and with donor DNA alone.

Monoclonal antibodies. A panel of monoclonal antibodies (Table 1) was used to detect epitopes on the surface of human

monocytes. The monoclonal antibodies MY4, B44.1, and LeuM3 were used to stain transformed recipient NIH-3T3 cells by fluorescence-activated cell sorting. Transformed cell populations selected with one of the antibodies were tested for reactivity with the entire panel. Antibodies Mol, Mo2, MY4, MY7, and MY9 were purchased from Coulter Immunology (Hialeah, FL). Antibodies LeuM3 and LeuM2 were purchased from Becton Dickinson Immunocytometry Systems (Mountain View, CA). Antibodies 61D3 and 63D3 were purchased from Bethesda Research Laboratories (Gaithersburg, MD). All other antibodies were gifts from the investigators who derived them. In addition, the monoclonal antibodies W6/32 (Accurate Chemical and Scientific Corp, Westbury, NY) and I2 (Coulter Immunology), specific for human HLA class I and class II molecules, respectively, were included in the test panel. Mouse myeloma protein UPC10 (IgG2a; Litton Bionetics, Kensington, MD) was used as a control for nonspecific binding.

Flow cytometry. Cell cultures were washed with Ca⁺⁺-MG⁺⁺-free phosphate-buffered saline (PBS) and treated with 3 mL of 10 µg/mL buffered trypsin (GIBCO) for five minutes at 37 °C to release the adherent cells. The cells were collected, centrifuged, and resuspended in staining medium (Dulbecco's modified Eagle's medium with 5% FCS, 6 mmol/L L-glutamine, 10 mmol/L HEPES, and 2 mmol/L sodium azide). Aliquots of 50 µL containing 1 × 10⁶ cells were washed once in the same medium and incubated for 30 minutes on ice with 50 µL of medium that contained a titrated excess of monoclonal antibody. After two washes, the cells were incubated for 30 minutes on ice in 50 µL of medium containing a titrated excess of affinity-purified, fluorescein-conjugated goat antibody to mouse immunoglobulins G and M (Tago Diagnostics, Burlingame, CA). The cells were then washed twice and resuspended at 2 × 10⁶ cells/mL in medium containing 0.25 mmol/L propidium iodide.

Transfected cells were analyzed and sorted with an EPICS 753 flow cytometer (Coulter Corporation, Hialeah, FL) as previously described.¹¹ Briefly, the brightest 2% to 4% of cells were sorted, grown to confluence, and resorted until a population of cells positive for antibody binding was isolated. The brightest 10% to 15% of fluorescence-positive cells were sorted several more times to enrich for transformed cells exhibiting the highest density of antigen expression. Subpopulations of peripheral blood leukocytes were analyzed by flow cytometry following simultaneous gating on both forward-angle and orthogonal light scatter from the cells. Fluorescence profiles were obtained from monocytes within the adherent cell fraction and from lymphocytes within the nonadherent cell fraction.

Southern blot analysis. Cellular DNAs were digested with the restriction endonucleases *Bam*HI, *Eco*RI, *Hind*III and *Sac*I. Digested DNA was subjected to electrophoresis in 0.8% agarose gels and transferred to nitrocellulose.³¹ A probe specific for human repetitive DNA sequences was prepared by self-annealing of boiled, sonicated human lymphoblastoid cell line DNA to a C₀t of 2 (where C₀ is the concentration of DNA in moles of nucleotide per liter and t is the time in seconds³²). Hybridization was performed at 60 °C at a monovalent cation concentration of 1.0 mol/L, and the double-stranded DNA was recovered by fractionation on hydroxylapatite.³² Human repetitive DNA was labeled to a specific activity of 1 × 10⁸ dpm/µg by nick translation³³ and used in blot hybridization under stringent annealing conditions.³⁴

Immunoprecipitation studies. Confluent flasks of transformed NIH-3T3 cells or adherent peripheral blood mononuclear cells were washed twice with cold PBS and incubated for 20 minutes at room temperature in 1 mL of PBS containing 5 mmol/L glucose, 3 µg lactoperoxidase, 5 mmol/L glucose oxidase (Sigma) and 1.0 mCi Na¹²⁵I (Amersham Corp, Arlington Heights, IL). Labeled cells were washed twice with PBS and lysed in 100 mmol/L Tris-HCl buffer (pH 7.6) containing 150 mmol/L NaCl, 20 mmol/L EDTA,

1% Triton X-100, 1% deoxycholate (DOC), 0.1% sodium dodecyl sulfate (SDS), 2% aprotinin (Sigma) and 1 mmol/L phenylmethylsulfonyl fluoride. Immunoprecipitation was performed as previously described¹¹ with rabbit antimouse immunoglobulin and protein A-Sepharose CL-4B (Pharmacia) used as the immunoabsorbent. Gel electrophoresis was performed under either nonreducing or reducing conditions on 10% SDS-polyacrylamide gels.³⁵ The molecular weights of the precipitated bands were estimated from the mobilities of known molecular weight standards (Sigma).

RESULTS

DNA-mediated gene transfer. High-molecular weight cellular DNA from normal human peripheral blood monocytes was cotransfected into mouse NIH-3T3 cells together with a plasmid containing the molecularly cloned *v-fms* gene from the McDonough strain of feline sarcoma virus. Cells expressing the *v-fms*-transforming gene were allowed to overgrow contact-inhibited NIH-3T3 cells, typically forming 250 to 750 discrete foci of morphologically transformed cells per 100 nanograms of cloned *v-fms* DNA. The transformed NIH-3T3 cells were subjected to sequential rounds of fluorescence-activated cell sorting to select those cells that bound the monoclonal antibodies MY4, B44.1, or LeuM3. The cells with the brightest fluorescence (top 2% to 4%) were sorted and grown to confluence; this procedure was repeated three to six times to isolate rare cells expressing human monocyte antigens (Fig 1). Positive cells showed equivalent binding of each of the three monoclonal antibodies, regardless of which antibody was used to select the positive cell population. As a control, one of the original populations of transfected cells was sorted with the monoclonal antibody W6/32, which recognizes human histocompatibility class I antigens.³⁰ Five successive rounds of sorting produced a cell population positive for W6/32 binding that did not bind any of the other monoclonal antibodies tested.

DNA was extracted from primary transformants selected for binding of B44.1 and again cotransfected with *v-fms* into NIH-3T3 cells. After three successive rounds of sorting with the monoclonal antibody B44.1, fluorescence-positive secondary transformants were isolated. DNA from secondary transformants was cotransfected with *v-fms* in three independent tertiary rounds of transfection. Pooled cells from each tertiary transfection were sorted after staining with either MY4 or B44.1. Three independently derived fluorescence-positive tertiary cell populations were isolated and plated in soft agar. Subclones derived from the resulting colonies were tested with an extensive panel of monocyte-specific monoclonal antibodies (Table 1) and demonstrated positive binding with ten reagents in addition to MY4, B44.1, and LeuM3 but not with 13 others (Fig 2). Concordant binding of these 13 monoclonal antibodies by independently derived, tertiary NIH-3T3 subclones indicated that these antibodies recognize epitopes on the product of a single human gene.

Southern blot analysis of human DNA in transformed mouse cells. Cellular DNAs from a primary transformant and two independently derived tertiary subclones were analyzed for the presence of human repetitive DNA sequences. The DNAs were digested with *Bam*HI, *Eco*RI, *Hind*III, and *Sac*I and analyzed by Southern blotting. As shown in Fig 3,

Fig 1. Selection of mouse NIH-3T3 cell transformants expressing the human monocyte membrane antigen recognized by the monoclonal antibody MY4. In each plot the fluorescence profile recorded after staining with MY4 (solid line) was compared with the fluorescence profile obtained with control mouse myeloma protein (dotted line). In panel A, pooled transformed NIH-3T3 cells were analyzed following cotransfection with human monocyte DNA; the fluorescence profile resulting from staining with MY4 was identical to the control profile. The brightest 2% of cells were selected by sterile sorting, grown up, and resorted. After two successive sorts, approximately 45% of the cells displayed high levels of MY4 fluorescence (B). After a fourth sort, >98% of the cells expressed the human monocyte cell surface antigen recognized by MY4 (C).

mouse NIH-3T3 DNA did not hybridize to the human repetitive sequence probe, whereas DNA from a primary transformant (lane 1) showed a diffuse hybridization pattern. In contrast, discrete human restriction fragments were shared by the two independently derived tertiary transfor-

Fig 2. Analysis by flow cytometry of cell surface binding by human monocyte-specific monoclonal antibodies to a cloned tertiary NIH-3T3 transformed cell population. Positive fluorescence profiles were obtained after staining of a representative subclone with monoclonal antibodies MY4 (—), B44.1 (— · — · —), LeuM3 (— · — · —), 26IF (— · — · —), AML-2-23 (— · — · —), and 63D3 (— · — · —). Similar positive profiles were observed after staining with FMC17, MOS1, MOP39, 77of, 23b, 49a, and 60bd. Staining with all other antibodies in the panel (Table 1) resulted in negative fluorescence profiles identical to that obtained with control mouse myeloma protein (· · · · ·).

mant. Analysis of the sizes of the shared human restriction fragments indicated that the gene encoding gp55 must be equal to or less than 50 kb.

Analysis of the gp55 gene product. Figure 4 demonstrates that a representative monoclonal antibody, 26if, specifically immunoprecipitated a polypeptide common to lysates of either normal human adherent peripheral blood mononuclear cells or one of the tertiary transformants. A second, weakly labeled polypeptide with a slightly lower molecular weight was also precipitated from lysates of tertiary transformants. The electrophoretic mobility of the major polypeptide was greater on nonreducing gels (63 kd, Fig 4) than on reducing gels (55 kd, analysis not shown). NIH-3T3 cells that were transformed by *v-fms* alone did not yield any specifically immunoprecipitated products (analysis not shown).

Monoclonal antibodies that reacted with transformed mouse cells expressing gp55 were also tested for reactivity with subpopulations of normal human peripheral blood leukocytes. Although these antibodies all recognize gp55 epitopes on transfected cells and human monocytes, their binding patterns with granulocytes and myeloid precursors are reportedly different. The six antibodies in our panel that were tested showed similar patterns of reactivity (Fig 5). Each reacted with gp55 expressed at high density by monocytes but did not bind to lymphocytes. Granulocytes consistently bound gp55-specific antibodies at much lower levels than did monocytes, but the binding was specific and significantly greater than that observed with a control mouse myeloma protein.

DISCUSSION

DNA-mediated gene transfer and cell-sorting techniques were used to isolate human DNA that included the gene encoding the monocyte-specific cell surface glycoprotein gp55. Southern blot analysis detected a limited complement of human DNA sequences shared by two independently derived tertiary mouse cell transformants, thus indicating that the gene encoding gp55 comprises fewer than 50 kb of human DNA. Concordant binding with each of 13 separate monoclonal antibodies indicates that each of these antibodies binds an epitope of gp55.

The presence of bona fide gp55 on transformed mouse cells was verified by immunoprecipitation with monoclonal antibody 26if, which precipitated proteins of identical size from radiolabeled plasma membranes of normal adherent mononuclear cells or the tertiary transformants. The presence of an additional, less efficiently labeled band of slightly lower molecular weight in lysates of monocytes and tertiary transformants suggests that a small fraction of cell surface gp55 molecules may have altered or incomplete posttranslational modification, the exact nature of which is unknown. The electrophoretic mobility of the major precipitated polypeptide on reducing gels (55 kd) agrees with published reports of a 55-kd glycoprotein immunoprecipitated by My4,⁴ a 50- to 66-kd glycoprotein by AML-2-23,⁹ and a 55-kd glycoprotein by 26if,⁶ but conflicts with accounts of a 200-kd protein precipitated by 63D3.²⁰ In our experiments, the antibodies LeuM3, 63D3 and FCM17 failed to yield specific immunoprecipitable products.

The binding specificities observed in this study are also strikingly similar to those reported for Mo2, which specifically immunoprecipitates a 55-kd glycoprotein from monocytes under reducing conditions.⁵⁻⁷ Additionally, Todd²² has shown that antibodies 26if, 77of, 60bd, and 49a, 23b, and 121nl all competitively block binding of directly fluorescently labeled Mo2 to monocytes. The lack of Mo2 binding to our tertiary transformants suggests that Mo2 might recognize an epitope that results from a posttranslational modification of monocyte gp55, which is altered in mouse cell transformants. Alternatively, Mo2 and 121nl might react with the product of another gene that assembles noncovalently with gp55 at the cell surface.

Reported experience with the 13 monoclonal antibodies that detected gp55 on our transformed cells indicates that all of the reagents bind to monocytes, with variable binding to granulocytes and none to lymphocytes. Accordingly, six gp55-specific antibodies that we tested (MY4, LeuM3, 63D3, 26if, B44.1, and AML-2-23) displayed strong specific affinity for peripheral blood monocytes as well as background levels of binding to lymphocytes and uniform but weak binding to granulocytes. These antibodies were previously reported to stain myeloid leukemia cells with monocytic morphology, consistent with their specificity for monocytes in populations of circulating leukocytes.¹⁰

The expression of gp55 by mature monocytes and macrophages suggests the possibility that it may mediate one of the diverse functional roles of these cells. Sorted 63D3-positive or 26if-positive cells from peripheral blood have been asso-

Fig 3. Southern blot analysis of human DNA sequences in transformed mouse cells. DNA samples were digested with the indicated enzymes before electrophoresis and transfer to nitrocellulose. Hybridization was performed by the use of radiolabeled human DNA consisting of highly reiterated sequence families. The lanes shown were composed from the same blot. DNA samples were obtained from a primary transformant (lane 1), control NIH-3T3 cells (lane 2), and two independently derived tertiary subclones (lane 3, 5, 7, 9 and lanes 4, 6, 8, 10, respectively). Major restriction fragments present in both tertiary subclones are indicated by triangles. The positions of bacteriophage lambda *Hind*III fragments of known length (noted in kilobase pairs) are indicated to the left of the figure.

Fig 4. Immunoprecipitation of gp55 from normal human monocytes and from mouse NIH-3T3 tertiary transformants. Cells were enzymatically surface radioiodinated with ^{125}I , detergent lysates were precipitated with antibody, and the radiolabeled immunoprecipitates were analyzed by SDS-polyacrylamide gel electrophoresis under nonreducing conditions. Lysates from normal human monocytes (lanes 1 and 2) or a tertiary NIH-3T3 subclone (lanes 3 and 4) were precipitated with monoclonal antibody 26if (lanes 1 and 3) or an isotype-matched control mouse myeloma protein (lanes 2 and 4). Positions of molecular weight standards are indicated.

ciated with accessory cell function and antigen presentation, respectively.^{36,37,7} Maliszewski et al⁹ concluded that gp55 is secreted by cultured monocytes and 1,25-dihydroxyvitamin D₃-treated HL60 cells that display monocytoid differentiation and is present in a slightly lower molecular weight form (44 to 50 kD) in normal serum.⁹ Thus, gp55 may be a polypeptide hormone precursor for a monokine of an as-yet-undetermined function. The transfer and expression of sequences encoding gp55 in a mouse genetic background should facilitate the characterization of this gene and its regulation and expression by normal and malignant cells.

Chronic Myelogenous Leukemia: Amplification of a Rearranged *c-abl* Oncogene in Both Chronic Phase and Blast Crisis

By Steven J. Collins and Mark T. Groudine

The specific genetic events that distinguish the blast crisis from the chronic phase cells of chronic myelogenous leukemia (CML) are unknown. The most common karyotypic change that occurs as CML evolves from chronic phase to blast crisis is the development of multiple Philadelphia (Ph¹) chromosomes, each of which is presumably harboring a translocated *c-abl* oncogene. We describe here a patient with CML who presented in lymphoid blast crisis with three Ph¹ chromosomes/metaphase associated with an amplified, rearranged *c-abl* oncogene fragment and high levels of the aberrant 8-kilobase *bcr-abl* transcript. This

rearranged *c-abl* fragment was amplified to a similar degree in both the patient's blast crisis cells and in his terminally differentiated granulocytes, but the level of the aberrant CML-specific *bcr-abl* transcript was some eight- to 16-fold higher in the blast crisis cells v the granulocytes. This analysis indicates that genomic amplification of a translocated *c-abl* oncogene, although perhaps important in the evolution of CML, nevertheless cannot, by itself, be the sole genetic event giving rise to blast crisis.

© 1987 by Grune & Stratton, Inc.

CHRONIC MYELOGENOUS LEUKEMIA (CML) is a clonal disorder involving a pluripotent stem cell from which granulocytes, erythrocytes, platelets, monocytes, macrophages, and B lymphocytes arise.¹ Over 90% of cases of CML exhibit the Philadelphia chromosome (Ph¹)(22q-), which results from a reciprocal translocation involving the distal portions of the q arms of chromosomes 9 and 22 and which is the most specific chromosome abnormality associated with any human malignancy. A prominent feature of CML is the distinct clinical phases of the illness. The relatively benign chronic phase, characterized by hyperplasia of terminally differentiated granulocytes, inevitably progresses to the blast crisis phase in which immature blasts predominate and that usually proves lethal.

Recent observations have provided considerable insight into the molecular genetics of the Ph¹ chromosome formation in CML. The *c-abl* oncogene is defined by virtue of its homology to *v-abl*, the transforming sequences of the Abelson murine leukemia virus.² In CML, this oncogene is translocated from its usual position on the distal end of the q arm of chromosome 9 to a relatively restricted region on the Ph¹ termed the breakpoint cluster region (*bcr*).^{3,4} As a result of this translocation, a hybrid *bcr-abl* transcript is generated.^{5,6} This abnormally large transcript (8.2 kilobase [kb]) probably codes for the abnormally large *abl*-related protein product (P210) that has been demonstrated in CML cells.^{7,8} Although the physiological function of the *c-abl* oncogene is unknown, these findings indicate that abnormalities in the structure and expression of this oncogene may be critical to the pathogenesis of CML.

Several lines of evidence indicate that enhanced expression of the altered *c-abl* oncogene may be important in the progression of CML from chronic phase to blast crisis. We have previously demonstrated that this oncogene is amplified some four- to eightfold in the K-562 CML blast crisis cell line.⁹ The development of multiple Ph¹ chromosomes, each of which is presumably harboring a translocated *c-abl* oncogene, is the most frequent karyotypic abnormality that occurs as CML evolves from the chronic phase to blast crisis.¹⁰ In addition, enhanced expression of the abnormal 8.2-kb *bcr-abl* hybrid transcript is noted in CML blast crisis cells v chronic phase cells.¹¹ Thus, one genetic event leading to enhanced expression of the translocated *c-abl* oncogene during progression of CML from the chronic phase to blast

crisis may be an increase in the copy number of the abnormal *bcr-abl* locus.

Is the enhanced expression of the aberrant 8.2-kb *bcr-abl* transcript due solely to the presence of the multiple Ph¹ chromosomes in certain CML cells? Is the presence of multiple Ph¹ chromosomes the main genetic change distinguishing CML chronic phase from blast crisis? We have been able to approach these questions by using a molecular genetic analysis of blast crisis and chronic phase cells from a patient with CML who presented in lymphoid blast crisis with multiple Ph¹ chromosomes/metaphase associated with amplification of a rearranged *c-abl* oncogene. Although there was a marked difference in the level of expression of the aberrant *bcr-abl* transcript in the blast crisis v the chronic phase cells, both of these cell types in this patient exhibited similar amplification of the rearranged *c-abl* fragment, which suggests that both the blast crisis and chronic phase cells harbored multiple Ph¹ chromosomes.

MATERIALS AND METHODS

Case Summary

The patient was a 42-year-old man who presented with a 1-month history of weight loss, malaise, fatigue, and headaches. His physical exam revealed pallor and splenomegaly without adenopathy. A complete blood cell count (CBC) revealed a hematocrit value (Hct) of 29, platelet count of 32,000, and a WBC count of 430,000 with

54% blasts, 3% lymphocytes, 4% monocytes, 3% nucleated RBCs, 10% myelocytes, 3% metamyelocytes (metas), 7% bands, and 16% segmented neutrophils (segs). A bone marrow aspirate and biopsy sample revealed a marrow packed with over 90% blasts that were terminal transferase-positive. Karyotypic examination revealed 52 XXY, +5, +11, +20, +3 Ph¹ in virtually all unstimulated metaphases. In contrast, phytohemagglutinin (PHA)-stimulated metaphases displayed a 46 XY karyotype. Therapy was initiated with oral hydroxyurea followed by two 3-week courses of vincristine, prednisone, and Adriamycin. Six weeks following initiation of therapy, the patient was noted to be in partial remission with an Hct of 28, platelet count of 56,000, and a WBC count of 7,000 with 3% blasts, 8% lymphocytes, 8% monocytes, 5% nucleated RBCs, 11% myelocytes, 12% metas, 15% bands, and 38% segs. The patient refused further chemotherapy and was discharged. Two months later he returned with a peripheral WBC count of 110,000 consisting of greater than 90% lymphoblasts. Therapy with oral hydroxyurea was reinstituted.

Cell Separation

At initial presentation the peripheral blood was diluted 1:1 with plain RPMI, layered over isolymph (Gallard/Schlesinger, Carle Place, NY), and spun at 1,800 rpm for 20 minutes. The interface cells were washed several times in RPMI and upon Wright staining were found to consist of over 85% blasts, with the remaining cells being predominantly myelocytes and metamyelocytes. The RBC-granulocyte isolymph pellet was brought to 25 mL with plain RPMI and mixed with 25 mL 3% dextran (T-500) in phosphate-buffered saline. The RBCs were allowed to sediment for 1 to 1.5 hours, and the supernate was harvested and the cells pelleted. The contaminating RBCs were lysed several times in 0.2% NaCl. The pelleted cells were then washed several times in plain RPMI and consisted of greater than 95% mature granulocytes.

After the chemotherapy-induced partial remission, peripheral blood was subjected to 3% dextran sedimentation followed by lysis of RBCs as described above. These cells consisted of approximately 70% metamyelocytes, bands, and segs, with the remaining cells consisting of mature lymphocytes and monocytes. There were fewer than 5% blasts in this cell population.

At the time of relapse, mononuclear cells were isolated following isolymph gradient centrifugation of peripheral blood. This fraction consisted of greater than 95% blasts.

DNA and RNA Extractions

DNA extractions from the various leukocyte populations were performed by digesting nuclei with protease K followed by phenol/chloroform extraction and ethanol precipitation as previously described.¹¹ RNA was extracted by homogenizing the cells in guanidine thiocyanate followed by ultracentrifugation through a cesium chloride cushion as described by Chirgwin et al.¹² Poly A⁺ RNA was selected by using oligo-dT cellulose.¹³

Southern, Northern, and Dot Blot Hybridizations

Restriction endonuclease digestion of genomic DNA was performed following manufacturer specifications. Southern and Northern blots were made following standard procedures.¹⁴ RNA dot blot analysis on the total cellular RNA was performed as previously described.¹¹ All blots were hybridized to nick-translated probes and subsequently washed under exactly the same conditions described previously.¹¹

Molecular Probes

5' abl. A molecular probe from the 5' end of the *c-abl* oncogene was cloned from a genomic library constructed from the K-562

CML blast crisis cell line.¹⁵ DNA from this cell line was partially digested with *Sau* 3A and fractionated by sucrose density gradient centrifugation, and the 15- to 23-kb DNA fragments were isolated. This DNA was ligated with *Bam*-digested EMBL 3 phage vector DNA, and the ligation mixture was packaged in vitro. Approximately 500,000 recombinant clones were screened with a nick-translated 550-bp *Hinc*II-*Sma*I fragment derived from the pAB1 sub9 plasmid, which contains a *v-abl* insert.¹⁶ This 550-bp fragment represents the most 5' sequences of *v-abl*. Following screening, ten positive clones were isolated and purified. One of these clones contained a 17-kb genomic insert that exhibited a restriction map similar to that of the previously published 5' end of *c-abl*,¹⁷ and from this clone a 0.3-kb *Hind*III-*Eco*R_I fragment free of human repetitive sequences was isolated and used as a molecular probe.

Genomic bcr probe. A 1.4-kb *Bgl*II-*Sst* human genomic fragment representing sequences within the *bcr* gene that are immediately 5' to the *bcr* itself¹⁸ was isolated from a normal genomic library. Details of the cloning procedure will be published elsewhere.

bcr cDNA probes. A 2-kb *bcr* cDNA clone was isolated from an HL-60 cDNA library screened with the aforementioned 1.4-kb *Bgl*II-*Sst* human genomic *bcr* fragment. A 700-bp *Pst* fragment near the 3' end of this clone that contains sequences that are represented in the normal *bcr* transcript but not in the aberrant *bcr-abl* transcript^{5,6,18} was utilized as a probe designated 3' *bcr*.

J_H. A 3.2-kb R_I-*Hind*III genomic probe cloned into pBR 322, which encompasses several of the exons within the J_H region of the immunoglobulin heavy chain locus, was obtained from Dr Roger Perlmutter.

v-abl. This probe is a 1.5-kb *Bgl*II fragment isolated from the *v-abl* insert of the pAB1 sub9 plasmid.¹⁶

Actin. The actin probe used is a 2.0-kb chick pA 1 β actin cDNA *Pst* fragment.¹⁹

In all cases the probes were purified from their respective vectors using the glass bead technique of Vogelstein and Gillespie²⁰ prior to nick translation and hybridization to the appropriate blots.

RESULTS

Cell Harvesting and Separation

We obtained peripheral blood cells from this patient at three different times during the course of his illness including (1) at initial presentation, at which time he had a WBC count of 430,000 with 54% blasts; (2) during a brief chemotherapy-induced partial "remission" when his peripheral count was 7,000 with >70% terminally differentiating granulocytes and <5% blasts; and (3) during relapse of blast crisis when his peripheral count rose to greater than 100,000 with over 90% blasts. At initial presentation, we separated the immature blast cells from the mature terminally differentiated granulocytes by isolymph gradient centrifugation as described in Materials and Methods. DNA and RNA were extracted from these cells as well as from the mature granulocytes isolated at the time of partial remission and from the immature blasts isolated at the time of relapse.

Lymphoid Nature of the Blast Crisis Cells

Many cases of CML blast crisis are B lymphoid in origin and exhibit immunoglobulin gene rearrangements.²¹ This patient's blast cells were positive for terminal transferase, thus suggesting their lymphoid origin. This was confirmed by Southern blot analysis of the blast cell DNA, which revealed several extra nongermline bands hybridizing to a heavy-chain immunoglobulin joining region probe (J_H) (Fig 1). The

Fig 1. Rearrangement of the immunoglobulin heavy-chain locus in the CML blasts. Genomic DNA was digested with *Bgl*II, electrophoresed in 1.0% agarose, transferred to nitrocellulose, and hybridized to a ^{32} P-labeled J_H probe specific for the immunoglobulin heavy-chain joining region. Samples include CML blasts isolated at presentation (lane 1); initial presentation granulocytes (lane 2); blasts isolated at relapse (lane 3); HL-60 cells, which exhibit the germline pattern (lane 4); and partial remission CML cells (lane 5). Rearranged fragments in the CML blasts are indicated by arrows.

identical restriction pattern was seen with this probe in DNA from both the blasts at initial presentation and at relapse (Fig 1). In contrast, predominantly the germline pattern was seen in the granulocyte populations isolated at initial presentation and during the chemotherapy-induced partial remission (Fig 1). Therefore these blots not only reveal the B lymphoid nature of the patient's blasts but also indicate that the separated granulocyte fraction is not contaminated with any significant number of these blasts.

RNA Analysis

RNA from the patient's blast and initial presentation granulocyte populations were subjected to Northern and dot blot analysis. The patient's blast cells exhibited the abnormal 8.2-kb *bcr-abl* hybrid transcript that has been previously described in Ph^1 chromosome-positive CML cells^{5,6,11} (Fig 2). The relative amount of this transcript is quite high and is comparable with that found in the K-562 cell line, which exhibits a four- to eightfold amplification of the *c-abl* oncogene (Fig 2). Although we did not obtain enough granulocyte RNA to perform Northern blots, we did note by RNA dot blot analysis a marked decrease of at least eightfold in the level of *abl*-related transcripts in the granulocyte population compared with the blasts (Fig 3). In addition, a similar eightfold decrease in the level of *bcr*-related transcripts was noted in the granulocyte population v the blasts. These results indicate that the level of *bcr-abl* hybrid transcripts is significantly higher in the blasts v the granulocyte

Fig 2. Enhanced expression of the aberrant 8.2-kb *bcr-abl* transcript in the CML blasts. Poly A⁺ RNA (5 μ g/line) was electrophoresed in a formaldehyde gel, transferred to nitrocellulose, and hybridized to a *v-abl* probe. The normal 7.4- and 6.6-kb transcripts as well as the aberrant 8.2-kb transcripts are noted. RNA samples are from K-562 (lane 1), HL-60 cells (lane 2), and the patient CML blasts (lane 3).

population in this patient. It is of interest that hybridization of this dot blot to a 3' *bcr* probe, which measures levels of *bcr* transcripts from normal chromosome 22 but does not detect *bcr-abl* hybrid transcripts, reveals a similar decrease in levels of normal *bcr* transcripts in the granulocyte populations v the blasts (Fig 3). As a control, we hybridized these same samples to an actin probe that revealed similar levels of actin-related transcripts in both (Fig 3).

c-abl Rearrangement and Amplification in Both Blasts and Granulocytes

We hybridized Southern blots of restriction digests of DNA from patient blasts and initial presentation granulocyte fractions with a 300-bp R_1 -*Hind*III *c-abl* probe (probe

Fig 3. Enhanced expression of both *abl*- and *bcr*-related transcripts in the CML blasts (row A) v initial presentation CML granulocytes (row B). The indicated quantities of RNA were dotted onto nitrocellulose and hybridized sequentially to the indicated probes. Between successive hybridizations, probes were removed from the blot by the addition of boiling water followed by cooling to room temperature with constant rocking. Exposure time was 20 hours for the *v-abl*, *bcr*, and 3' *bcr* probes and 4 hours for the actin probe. The 2-kb *bcr* cDNA probe recognizes both normal *bcr* transcripts as well as *bcr-abl* fusion transcripts. The 700-bp 3' *bcr* probe recognizes only normal *bcr* transcripts.

B) located within a 12-kb *Bgl*II fragment on chromosome 9 at the 5' end of *c-abl* (Fig 4). This probe detected an extra fragment in both the blast and granulocyte DNA digests, thus indicating that the break on chromosome 9 in this patient lies within this 12-kb *Bgl*II fragment and that both the blast and granulocyte subpopulations harbor a similar chromosome 9 breakpoint (Fig 4). In both the blast and

granulocyte fractions, this probe hybridizes more intensely to the rearranged *Bgl*II fragment than to the germline fragment, which suggests that the rearranged *c-abl* fragment is amplified in this patient. We also noted a rearranged and amplified *Kpn*I fragment in genomic digests of blast and granulocyte DNA hybridized to a chromosome 22 probe (probe A) located just 5' to the breakpoint cluster region on

Fig 4. Amplification and rearrangement of *abl* and *bcr* sequences in CML blasts and granulocytes. Genetic maps of the *bcr* region on chromosome 22 (A), the 5' *c-abl* region on chromosome 9 (B) and the 9:22 Ph¹ breakpoint region on the Ph¹ chromosome in this particular patient (C) are shown. These maps were derived from data from references 4, 5, and 17 and from our own mapping data. The approximate breakpoints on chromosomes 22 and 9 in this patient have been previously mapped and are indicated by arrows. Probe A is a 1.4-kb *Bgl*II-*Sst* chromosome 22 fragment located immediately 5' to the breakpoint cluster region (BCR) and hybridizes to a 19-kb *Kpn*I germline fragment as indicated in A. Probe B is a 0.3-kb R₁-*Hind*III fragment located in the 5' *c-abl* region of chromosome 22 that hybridizes to a 12-kb *Bgl*II germline fragment as indicated in B. *c-abl* exons are denoted by ▨. These probes were hybridized to Southern blots of genomic digests of CML DNA from patient blasts (lanes 1 and 3) and from initial presentation patient granulocytes (lanes 2 and 4). Lanes 1 and 2 are *Bgl*II digests; lanes 3 and 4 are *Kpn*I digests. In both blasts and granulocytes probe B identifies the 12-kb germline *Bgl*II fragment as well as a rearranged, amplified 7.5-kb fragment as indicated (lanes 1 and 2). Probe A identifies the 19-kb *Kpn*I germline fragment as well as a rearranged, amplified 7.8-kb fragment as indicated (lanes 3 and 4). These rearranged fragments are 9:22 junction fragments as indicated in C. Densitometric scanning reveals a ratio of rearranged:germline fragment of approximately 6:1 using probe B (lanes 1 and 2) and 10:1 using probe A (lanes 3 and 4) in both the blast and granulocyte DNA digests.

chromosome 22 (Fig 4). Thus, both *bcr* (chromosome 22) and *c-abl* (chromosome 9) sequences are amplified and rearranged in this patient and this amplification/rearrangement most likely reflects the multiple Ph¹ chromosomes/metaphase that were demonstrated in this patient's leukemic cells. Notably, with both these probes the ratio of the intensity of hybridization of the rearranged to the germline fragments is essentially the same when comparing the blast and granulocyte DNA digests, thus indicating that the rearranged *c-abl* gene is amplified to a similar degree in both (Fig 4).

DISCUSSION

The recent identification of specific genes that are involved in Ph¹ chromosome formation in CML now allows the identification of cells harboring this marker chromosome by Southern blot hybridization of restriction digests of genomic DNA.^{3,4} The major advantage of this technique is that metaphases from immature, proliferating cells are no longer essential for analysis, since the assay can be performed with any cellular DNA at any particular level of cell differentiation. We utilized this approach to analyze various cell populations of a patient who presented with CML in blast crisis. Several somewhat unusual aspects of this patient's illness made the analysis particularly useful. At presentation there were a significant number of terminally differentiating granulocytes in his peripheral blood in addition to the lymphoid blast crisis cells, which allowed for ready separation of distinct CML cell subpopulations. Moreover, Southern blot analysis readily distinguished these lymphoid blast crisis cells from the terminally differentiating granulocytes, since only the blasts exhibited a rearrangement of the immunoglobulin heavy-chain J_H locus. In addition, a karyotype analysis of bone marrow blasts in this patient revealed three Ph¹ chromosomes/metaphase. The breakpoint on chromosome 9 that contributed to the Ph¹ formation in the leukemic cells was relatively close to the *v-abl* homologous region such that Southern blots revealed a rearranged *c-abl* fragment utilizing a 5' *c-abl* probe. (Only 15% to 20% of CML patients exhibit a breakpoint this close, with most CML chromosome 9 breakpoints occurring much further 5' to the *v-abl* homologous region.)^{4,22} This rearranged 5' *c-abl* fragment was amplified in this patient's blast cells, most likely reflecting the presence of the multiple Ph¹ chromosomes/metaphase. Thus using this 5' *c-abl* probe, we were not only able to determine the presence of the Ph¹ in various cell populations but could also, by comparing the intensity of hybridization of the amplified, rearranged fragment to the germline fragment, estimate the number of Ph¹ chromosomes that each isolated cell population harbors.

We isolated blast crisis cells from this patient at the time of initial presentation and at the time of relapse. We also isolated terminally differentiated granulocytes at initial presentation and during a chemotherapy-induced partial "remission" when the peripheral blood blast cell population fell below 5%. The morphologically immature blasts displayed a rearrangement of the immunoglobulin heavy-chain locus that indicated a B lymphoid blast crisis, whereas the mature granulocytes exhibited a germline immunoglobulin heavy-

chain pattern and were therefore representative of chronic phase cells. If one of the major genetic events that distinguishes these lymphoid blast crisis cells from the terminally differentiated chronic phase granulocytes is the development of multiple Ph¹ chromosomes with concomitant amplification of the rearranged *c-abl* fragment, then one would predict that the terminally differentiated granulocytes would not display amplification of the rearranged *c-abl* fragment (ie, precursors of these granulocytes display a single Ph¹). However, our Southern blots show that this is clearly not the case, since this rearranged *c-abl* fragment is amplified to a similar degree in both the blast and granulocyte cell populations. Indeed, these Southern blots indicate that the terminally differentiated granulocytes also harbor multiple Ph¹ chromosomes. Therefore, the development of multiple Ph¹ chromosomes per se cannot be the sole genetic event that leads to the blast crisis phenotype, and one would predict that there are other genetic factors besides multiple Ph¹ chromosomes that distinguish the blast crisis from the chronic phase cells.

One potential problem in interpreting our Southern blots is that the enhanced hybridization of the *bcr* and *abl* probes to the rearranged fragments may be secondary to preferential transfer from the agarose gel to nitrocellulose of the smaller, rearranged fragments compared with the larger, germline fragments. Indeed since the rearranged *bcr* and *abl* fragments most likely are present on each individual Ph¹ chromosome, one would predict a ratio of intensity of hybridization of rearranged:germline fragment of 3:1 with these probes (ie, three Ph¹ chromosomes/one normal chromosome 9 or 22/metaphase). However, our densitometric scanning indicates a hybridization intensity ratio of 6:1 with the 5' *c-abl* probe and 10:1 with the *bcr* genomic probe (Fig 4), which suggests that there indeed has been preferential transfer of the smaller rearranged fragments in these blots. However, the important observation is that the hybridization intensity ratios of rearranged:germline fragments using both *abl* and *bcr* probes are virtually identical in the blasts (which by karyotypic analysis harbor three Ph¹ chromosomes/metaphase) and the chronic phase granulocytes. Thus even though preferential transfer of the smaller rearranged fragments is probably present in these blots, this does not interfere with our conclusion that the chronic phase granulocytes are similar to the blast crisis cells in harboring multiple Ph¹ chromosomes.

Although we noted amplified, rearranged *c-abl* sequences in both the lymphoid blast crisis cells and the chronic phase granulocytes in this patient, the blast crisis cells had an eight- to 16-fold greater level of *bcr-abl*-related transcripts than the chronic phase granulocytes (Fig 3). Thus, the presence of amplified *c-abl* sequences per se within the genome of certain CML cells does not necessarily lead to enhanced expression of these sequences. What controls the expression of the aberrant *bcr-abl* transcript in CML? The *c-abl* oncogene in CML is translocated into the *bcr* gene on the Ph¹, and transcription of this oncogene may then come under control of those factors that normally control transcription of the intact *bcr* gene on the normal chromosome 22. Consistent with this hypothesis is our finding that there is a decrease in the normal chromosome 22 *bcr* transcripts in the CML granulocytes v blast crisis cells that is almost

exactly proportional to the decrease in the level of Ph¹ chromosome *bcr-abl*-related transcripts in these cells (Fig 3). Indeed, one hypothesis to explain the progression of CML to blast crisis is that a subset of Ph¹-positive CML cells harboring trans-activating factors specific for the normal *bcr* gene might also develop enhanced expression of the aberrant *bcr-abl* transcript and presumably gain a selective growth advantage over other Ph¹-positive CML cells that do not harbor such specific factors. This model would explain how some CML cell populations (for instance, the granulocytes from this patient) would not display high levels of the *bcr-abl* transcript even though they harbor multiple Ph¹ chromo-

somes. An alternative hypothesis to explain the evolution of CML is that a further genetic event or mutation, perhaps involving another oncogene in addition to the Ph¹ translocation, gives rise to blast crisis.

ACKNOWLEDGMENT

I am grateful to Drs Jean Wang and Roger Perlmutter for gifts of the pAB sub9 *v-abl* and J_H probes, respectively. I wish to thank LeMoyne Mueller and Monique Howard for excellent technical assistance, Lynn Guthrie for editorial assistance, and Donella Sawin for assistance in preparation of the manuscript.

Augmentation of In Vitro Human Marrow Erythropoiesis Under Physiological Oxygen Tensions Is Mediated by Monocytes and T Lymphocytes

By Rukmani Pennathur-Das and Lee Levitt

Tissue and marrow (BM) in vivo O_2 tensions have been estimated at 23 to 40 mm Hg (3% to 5% O_2). We have investigated cellular regulation of burst-forming units-erythroid (BFU-E) under 5% O_2 . BFU-E from BM mononuclear cells (MNC) were cultured in methylcellulose medium and erythropoietin (Ep) $\pm$ monocyte-conditioned medium (MoCM, a source of burst-promoting activity, BPA) in the presence or absence of autologous T cells (T) and/or monocytes (M ϕ) under either 5% or 21% O_2 after depletion of T (MNC-T), M ϕ (nonadherent buoyant cells, NAB) or both T and M ϕ depletion (NAB-T). MNC BFU-E growth under 5% O_2 was augmented over 0.1 to 1.5 U/mL of Ep. BFU-E augmentation under 5% O_2 was abolished by depletion of BM M ϕ , T, or both from MNC. The addition of MoCM affected neither a BFU-E increase under 5% O_2 nor the abrogation of that increase upon T or M ϕ depletion. The addition of 5% to 20% M ϕ or 10% to 20% T to NAB-T failed to restore the BFU-E increase under 5% O_2 . However, BFU-E augmentation under 5% O_2 was reestablished when 10% autologous M ϕ , 10% T, or 10% T plus 10%

M ϕ were added back to marrow NAB, MNC-T, or NAB-T. BM BFU-E was not augmented in the presence of varying concentrations of catalase, superoxide dismutase, or reduced glutathione at 21% O_2 ; moreover, BFU-E augmentation was maintained at 5% O_2 relative to 21% O_2 in the presence of each of these antioxidants. CM prepared under 5% or 21% O_2 from BM M ϕ , T, or M ϕ plus T were assessed for BPA against BM NAB-T using a sensitive BPA assay incorporating delayed Ep addition to cultures. Only CM from mixtures of M ϕ and T cells at 5% O_2 demonstrated potent BPA; little or no BPA was detected with T or M ϕ CM at 5% O_2 and at 21% O_2 or T and M ϕ CM at 21% O_2 . The sensitivity of NAB-T BFU-E to exogenous BPA was virtually identical at 21% and 5% O_2 . These results indicate that human BM BFU-E are augmented under 5% O_2 and that T cells and M ϕ together mediate that augmentation by collaborating to produce BPA-like activity in response to physiological O_2 tensions.

IN VITRO INVESTIGATIONS of hematopoiesis have to date been performed at atmospheric oxygen tensions (140 to 150 mm Hg, 21% O_2). However, tissue oxygen tensions and, in particular, bone marrow oxygen tension are far below 140 mm Hg, the partial pressure of oxygen at room air. Guyton estimates the tissue oxygen tension in vivo to be approximately 40 mm Hg.¹ Tondevdol et al have measured medullary cavity oxygen pressures within canine long bones and have reported values between 23.5 and 27.7 mm Hg (3% to 4% O_2) at arterial pressures of 75 to 110 mm Hg. When the arterial pressure dropped below 75 mm Hg, the bone medullary oxygen tension dropped still further to 14 to 18 mm Hg.^{2,3} Thus, the true physiological pO_2 in the marrow is much closer to 5% O_2 than 21% O_2 , and in vivo hypoxic conditions would be expected to cause further decrements in marrow oxygen tension.

Although it has been known for a number of years that compensatory in vivo erythropoietic responses to hypoxia are induced by increased erythropoietin (Ep) production⁴ and that tissue oxygen delivery can be augmented through increased production of 2,3-diphosphoglyceric acid,⁵ in vitro regulation of erythropoiesis under less than atmospheric oxygen tensions has not been investigated in detail. Bradley et al have reported an increased size and number of hematopoietic granulocyte-macrophage progenitor cells (CFU-GM) when murine marrow is cultured in agar and incubated at 6.8% O_2 .⁶ Rich and Kubanek have reported increased growth of both early (BFU-E) and late (CFU-E) erythroid progenitors when murine marrow cells were cultured at 5% O_2 .⁷ They attributed this increased erythroid-plating efficiency to lowered oxygen toxicity at 5% O_2 and observed that antioxidants augmented erythroid colony formation when marrow cells were cultured under atmospheric oxygen tensions. However, antioxidants did not reproduce the degree of erythroid augmentation observed at 5% O_2 . Rich and Kubanek speculated that either a further reduction in oxygen toxicity or recruitment of additional erythroid colony-form-

ing cells may occur when murine marrow is cultured at physiological oxygen tensions. Broxmeyer in a preliminary report has recently observed increased human granulocyte-macrophage progenitor (CFU-GM) formation at 5% O_2 and has suggested that CFU-GM progenitors demonstrate increased sensitivity to granulocyte-macrophage colony-stimulating factors (GM-CSF) when grown at 5% O_2 .⁸ He also observed an increased release of GM-CSF from human peripheral blood macrophages cultured at low O_2 tensions. Investigators have also recently reported that human marrow erythropoiesis is augmented under low pO_2 tensions, but the mechanism of that augmentation has not been well delineated.^{9,10}

In this study, we have investigated the effects of physiological (5%) O_2 tensions on human marrow erythropoiesis and have evaluated specific cellular contributions to erythroid progenitor growth under physiological oxygen tensions. Our

results indicate that erythroid colony formation is enhanced when human marrow is cultured at 5% O₂ and that the erythropoietic augmentation observed at physiological oxygen tensions is mediated by a cooperative interaction between monocytes (M ϕ) and T cells.

MATERIALS AND METHODS

Bone marrow procurement and cell separation methods. All studies were approved by the Stanford University Human Experimentation Committee. All patients were advised of the procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent. Two to 4 mL of aspirate was drawn into heparinized tubes, diluted in phosphate-buffered saline (PBS), layered over Ficoll-Hypaque gradients (density, 1.077 g/mL), and centrifuged at 400 g for 30 minutes, and the interface buoyant mononuclear cells (MNC) were collected and washed three times in Iscove's modified Dulbecco's medium (IMDM). These cells are subsequently referred to as MNC. M ϕ were removed by two consecutive (45 minutes each) adherence procedures at 37 °C in polystyrene tissue culture dishes using IMDM with 7.5% fetal calf serum (FCS) at cell concentrations of 10⁷ cells/mL.^{11,12} Nonadherent buoyant cells (NAB) obtained in this manner contained <2% M ϕ by esterase stain and immunofluorescent labeling with LeuM3 monoclonal antibody (MCAB). Adherent MNC (>95% M ϕ by esterase staining and LeuM3 MCAB immunofluorescence), were isolated by gentle scraping with a rubber policeman after vigorous washing to remove the loosely bound cells.

T cells were removed from the marrow by solid-phase immunoabsorption "panning."¹¹ In this method, polystyrene Petri dishes were coated with 100 μ g of affinity-purified goat antimouse IgG (Tago, Burlingame, CA) diluted in 10 mL of 0.05 mol/L TRIS buffer. After a 40-minute incubation at 23 °C, the buffer was decanted and the dishes gently washed five times with PBS. Cell suspensions (20 $\times$ 10⁶ cells in 75 μ L IMDM) were coated with 50 to 100 μ g of Leu1 pan-T MCAB, incubated at 4 °C for 20 minutes, centrifuged, and then added to the antibody-coated dish (indirect panning) and incubated for 70 minutes at 4 °C. Cells bound to the coated dish and nonbound cells were separately recovered by differential elution with cold PBS-1% FCS. In almost all cases, >95% of the bound cells and <2% of the nonbound cells stained positively by cytofluorographic analysis with a combination of two or three separate (Leu1, Leu4, and Leu5) pan-T MCABs. In control experiments, cultures of M ϕ or T cells alone never yielded >2% BFU-E per 10⁵ cells plated.¹²

Assay systems for hematopoietic progenitor cells. Marrow MNCs (0.5 to 1.5 $\times$ 10⁵/mL) were cultured with 0.5 U/mL of human urinary Ep (1,140 National Institutes of Health [NIH] 1,140 U/mg protein) in triplicate 0.25-mL aliquots containing 1.1% methylcellulose, 50 μ mol/L 2-mercaptoethanol, and 15% to 30% FCS with or without 1% bovine serum albumin (BSA) and MoCM-conditioned medium (MoCM, a medium conditioned by a T lymphoblast cell line containing both colony-stimulating activity and erythroid burst-promoting activity [BPA]¹³). Cells were incubated at 37 °C and 5% CO₂ in either 21% O₂ (room air) or 5% O₂ in modular chambers (Billips & Rothenberg, Del Mar, CA). Colonies were scored on days 12 to 14 to assess committed erythroid (BFU-E) progenitor cells as previously described.¹²

The percent augmentation of BFU-E growth was calculated based upon the following formula:

$$\text{Percent augmentation} = \frac{(\text{no. colonies at 5\% O}_2) - (\text{no. colonies at 21\% O}_2)}{(\text{no. colonies at 21\% O}_2)}$$

In some experiments, enriched populations (1 to 10 $\times$ 10⁴ cells/mL) of either marrow M ϕ or marrow T cells were added back to cultures containing 1 to 2 $\times$ 10⁵ autologous marrow MNCs previ-

ously depleted of monocytes and/or T lymphocytes. Control groups, concurrently assessed for progenitor cell growth, included enriched marrow T cells or M ϕ alone and unfractionated marrow MNCs; the cultures were grown separately but simultaneously and assayed in the presence and absence of Ep $\pm$ MoCM for the growth of marrow BFU-E.

Establishment and monitoring of oxygen tensions in cultures. Low (5%) O₂ cultures were set up using gas-tight modular chambers that can be flushed with any desired gas mixture. Multiwell tissue culture plates were placed in modular chambers and flushed with 5% O₂, 5% CO₂, and 90% N₂ for five minutes. Plates filled with sterile water were placed in the modular chambers to provide humidity. The residual O₂ in multiwell plates was allowed to equilibrate with the gas phase in the chambers for one to two hours, after which the modular chambers were flushed once again with the 5% O₂ gas mixture. The pO₂ and pCO₂ in the chambers were monitored daily and maintained at 5% $\pm$ 0.5% for 14 days of culture. Control cultures were maintained at 21% O₂ in modular chambers by flushing with a gas mixture of room air with 5% CO₂.

Preparation of CM. Subpopulations of purified bone marrow T lymphocytes or M ϕ were incubated in IMDM with 50 μ mol/L 2-mercaptoethanol at either 21% O₂ or 5% O₂ for two days at a concentration of 2 $\times$ 10⁵ cells/mL. CM were also prepared from a mixture of M ϕ and T cells at M ϕ :T ratios of 1:6 (total cells, 2 $\times$ 10⁵). CM supernatants were harvested, spun at 1,800 g for ten minutes, and either used on the day of harvest or stored at 4 °C until testing. CM were assessed at 12% vol/vol against marrow MNCs depleted of both M ϕ and T cells (NAB-T).

Assessment of CM for BPA. To improve the detection of BPA in these CM, we plated NAB-T cells in 30% FCS and 1% BSA in the presence of CM and delayed the addition of Ep to cultures until day 3.¹⁴ Negative controls consisted of wells plated in the presence of IMDM but in the absence of any added CM, and the addition of 1% MoCM was used as a positive control. In control experiments, 10 $\pm$ 3 BFU-E and 2 $\pm$ 2 CFU-GM were formed per 10⁵ cells in the absence of MoCM, whereas 118 $\pm$ 9 BFU-E and 142 $\pm$ 7 CFU-GM were formed in the presence of 1% MoCM.

Effects of antioxidants on BFU-E at 21% and 5% O₂. The effects of antioxidants on BFU-E were assessed by culturing bone marrow MNCs in the presence and absence of 0 to 10 mmol/L reduced glutathione (Sigma Chemical Company, St Louis), 0.1 to 1,000 μ g/mL of superoxide dismutase (Biotics Research Corp, Houston), or 0 to 100,000 U/mL of catalase (Sigma) at both 21% and 5% O₂. Control experiments using superoxide dismutase in a system containing acetaldehyde-xanthine oxidase plus reduced cytochrome c indicated that the superoxide dismutase used in our culture system was an efficient superoxide scavenger. Similar concentrations of antioxidants have been used to successfully inhibit free radical-induced damage to red cell membrane and to inhibit up to 90% of hydroxyl radical generation by human phagocytes.¹⁵ Glutathione was always freshly prepared for each assay.

Assessment of erythroid progenitor sensitivity to BPA under varying culture oxygen tensions. We assessed the differential sensitivity of marrow BFU-E to exogenous BPA (MoCM) at 21% and 5% O₂. Cultures (n = 4) were established with marrow target cells depleted of both M ϕ and T cells, in 15% FCS in the absence of BSA, and in the presence of 0% to 10% MoCM. In control experiments performed at both 21% and 5% O₂, the addition of 0.2% to 1.0% MoCM produced a three to fivefold increment in marrow BFU-E. The percent change in BFU-E under 5% O₂ relative to 21% O₂ was calculated at each concentration of MoCM. Both the absolute number of BFU-E and the percent change observed at 5% O₂ relative to 21% O₂ were compared at MoCM concentrations of 0% to 10%.

Statistics. The two-sample unpaired Student's *t* test was used in statistical analysis of the data.¹⁶

Table 1. Augmentation in Human Marrow BFU-E at 5% O₂

Ep (U/mL)	No. BFU-E per 100,000 Cells*										Percent Change †
	21% O ₂	5% O ₂	21% O ₂	5% O ₂	21% O ₂	5% O ₂	21% O ₂	5% O ₂	21% O ₂	5% O ₂	
0.1	84	122	163	215	47	67	71	111	32	67	44.0 ± 4.5
0.2	138	226	187	267	32	64	97	147	72	115	62.0 ± 12.3
0.5	219	326	175	336	72	123	125	138	112	163	54.8 ± 7.9
1.0	182	250	232	347	96	138	103	120	170	199	33.0 ± 6.1
1.5	163	248	—	—	134	210	91	128	136	195	39.8 ± 8.0

Each value represents the mean ± SEM of results from five separate experiments, each involving a different normal marrow donor. Colony numbers are indicated for only three representative experiments to simplify the table.

*Mean value for BFU-E per 10⁵ marrow mononuclear cells; each experiment is plated in triplicate.

†Percent change = (no. BFU-E at 5% O₂ - no. BFU-E at 21% O₂) × 100/no. BFU-E at 21% O₂.

RESULTS

Augmentation of marrow erythropoiesis at 5% O₂. Physiological oxygen tensions (5% O₂) augmented in vitro bone marrow erythropoiesis relative to marrow cultures grown at 21% O₂. The increase in erythropoiesis, as detected by an augmentation in the number of human burst-forming units (BFU-E) grown from marrow MNC, was observed over a wide range of Ep concentrations (0.1 to 1.5 U/mL) (Table 1 and Fig 1). Table 1 lists five experiments in which BFU-E augmentation is demonstrable at each Ep concentration used along with the mean BFU-E augmentation. There was a 33% to 62% (n = 5) increase in BFU-E when marrow MNC were cultured at 5% O₂ compared with cultures established at room air (21% O₂) ($P < .001$). This increase appeared to be independent of Ep. No erythroid colonies were detected under 5% O₂ in the absence of added Ep (data not shown). The increase in BFU-E at 5% O₂ was not significantly ($P > .05$) diminished by the addition of MoCM, a potent source of exogenous BPA; in nine experiments, a 39% ± 10% increase in BFU-E was observed at 5% O₂ (over 21% O₂) in the presence of 0.5 U/mL of Ep plus 1% MoCM compared with a 55% ± 8% increase in BFU-E when paired, autologous marrow cells were concomitantly grown in the presence of 0.5 U/mL of Ep alone. The increase in BFU-E was maintained even in the presence of 2% to 10% MoCM (data not shown). In control experiments, the maximal BFU-E expression was observed between 0.5% and 2.0% MoCM (data not shown).

Effect of Mφ and/or T cell depletion on augmentation of marrow erythropoiesis under 5% O₂. Depletion of Mφ from marrow MNC (NAB) abolished the augmentation in BFU-E growth under 5% O₂ over the entire range of Ep concentrations studied (Fig 1) ($P < .001$). Similarly, no augmentation was observed under 5% O₂ when nonadherent marrow cells were cultured in the presence of MoCM plus Ep (Fig 2). Augmentation of erythropoiesis was also abolished when marrow MNC were depleted of T lymphocytes. Marrow T cell depletion (MNC-T) abrogated erythropoietic stimulation whether cultures were established with Ep alone or with MoCM plus Ep (Fig 2). No augmentation in erythropoiesis was noted at 5% O₂ relative to 21% O₂ when marrow MNC were depleted of both monocytes and T cells (NAB-T) and cultured in the presence of Ep alone or MoCM plus Ep (Fig 2).

Augmentation of CFU-GM at 5% O₂. Physiological (5%) O₂ tensions also augmented CFU-GM growth (186% ± 64% increase over control) from marrow MNC relative to marrow MNC grown under 21% O₂ (Table 2). However, the removal of T cells (110% ± 17% increase over control), Mφ (133% to 54% increase over control), or both T cells and Mφ (106% ± 26% increase over control) did not abolish the granulopoietic augmentation under 5% O₂ (Table 2).

Lack of BFU-E augmentation at 5% O₂ following the addition of Mφ or T cells to autologous, nonadherent T cell-depleted marrow MNC. We assessed BFU-E growth at 5% and 21% O₂ following the addition of either 0% to 20%

Fig 1. Augmentation in erythroid progenitors (BFU-E) cultured from human bone marrow MNC at various Ep concentrations and the effect of marrow MNC depletion on erythropoietic augmentation at 5% O₂. Results are expressed as means ± SEM of the percent change in BFU-E observed at 5% O₂ compared with 21% O₂ (see Materials and Methods) and are derived from five to nine separate experiments. At 0.5 U/mL Ep in a representative experiment, 175 and 336 BFU-E/10⁵ are obtained at 21% O₂ and 5% O₂, respectively, with marrow MNC, whereas 190 and 182 BFU-E/10⁵ are obtained at 21% O₂ and 5% O₂, respectively, with marrow NAB.

Fig 2. Effect of M ϕ , T cells, and exogenous BPA (MoCM) on erythropoietic augmentation at 5% O₂. Human bone marrow MNC were plated before and after depletion of monocytes (NAB) by two consecutive adherence separation procedures, after depletion of T cells with immunoabsorbant panning with Leu1 pan-T MCAb (MNC-T), or after depletion of both Mo and T cells (NAB-T) by a double-adherence procedure followed by panning. Results are expressed as means $\pm$ SEM of the percent change in BFU-E observed at 5% O₂ compared with those at 21% O₂ (see Materials and Methods) and are derived from seven to ten separate experiments.

T cells or 0% to 20% M ϕ to autologous marrow MNC depleted of both Mo and T cells. As demonstrated in Table 3, the addition of 0% to 20% T cells to nonadherent, T cell-depleted marrow MNC failed to restore erythropoietic augmentation at 5% O₂ ($P > .5$); no BFU-E augmentation was achieved even after the addition of 40% T cells (data not shown). Similarly, the addition of 10% to 20% autologous M ϕ to M ϕ -free, T-depleted marrow MNC also failed to restore augmentation of erythropoiesis under 5% O₂ ($P > .5$) (Table 3).

Augmentation of BFU-E under 5% O₂ following the addition of M ϕ to nonadherent marrow MNC or the addition of T cells to T cell-depleted marrow MNC. Augmentation of marrow erythropoiesis under 5% O₂ was restored by reconstituting nonadherent, T cell-depleted marrow MNC with both autologous M ϕ and T cells. Thus, the addition of 5% to 50% autologous M ϕ to M ϕ -free marrow MNC resulted in a 26.2% to 43.0% ($P < .01$) increase in BFU-E under 5% O₂ compared with control M ϕ -repleted cultures established from the same donor but grown under 21% O₂ (Table 4). Similarly, the addition of 10% T cells to autologous, T cell-depleted marrow MNC augmented erythropoiesis under 5% O₂ by 56.2% $\pm$ 14.1% ($P < .01$). The addition of 10% M ϕ plus 10% T cells to autologous, nonadherent T cell-depleted marrow target cells also restored BFU-E augmentation under 5% O₂ (-4.3% $\pm$ 10.6% to 76.2% $\pm$ 10.5%) ($P < .001$). These results, in toto, indicate that both M ϕ and T cells are required for erythropoietic augmentation at 5% O₂.

Effects of CM prepared from purified T cells and M ϕ at 5% or 21% O₂ on BFU-E growth from NAB-T. To confirm the role of T cells and monocytes in mediating BFU-E augmentation under 5% O₂, we prepared two-day CM from marrow M ϕ and/or T cells at 5% O₂ and 21% O₂ and assessed these CM for BPA against nonadherent, T cell-depleted marrow MNC. We delayed the addition of Ep to cultures until day 3 to increase the sensitivity of the BPA assay by eliminating Ep-sensitive BFU-E. Under these conditions, only minimal numbers ($10 \pm 3/10^5$ NAB-T) of BFU-E were obtained in the absence of MoCM; a substantial increase ($118 \pm 9/10^5$ cells plated) was observed upon the addition of exogenous BPA (1% MoCM). CM prepared from either T cells or M ϕ alone did not provide erythroid potentiating activity at either 5% or 21% O₂ (Fig 3). However, CM prepared under 5% O₂ from T cell-M ϕ mixtures provided potent ($P < .001$) BPA activity compared with identical M ϕ -T cell mixtures prepared under 21% O₂ (Fig 3) ($n = 4$). CM prepared for 24 hours from mixtures of T cells and M ϕ under 5% and 21% O₂ and assessed against autologous marrow NAB-T target cells gave similar results in which only CM prepared with T cell-M ϕ mixtures under 5% O₂ provided potent BPA activity. The low erythroid potentiation obtained from T cell-M ϕ CM established under 21% O₂ most likely reflects the short preparation time of the CM (48 hours) as well as the relatively low number (2×10^5 cells/mL) of cells used in CM preparation.

Assessment of these CM for CFU-GM showed low CSF-GM activity. In the absence of exogenous CSF, only 2 ± 1

Fig 3. Effect of CM prepared at 5% or 21% O₂ on erythroid progenitors (BFU-E) cultured from nonadherent, T cell-depleted target cells. CM were prepared for one to two days under either 5% or 21% O₂ using either marrow M ϕ (2×10^5 cells/mL) or T cells (2×10^5 cells/mL) alone or mixtures of both M ϕ and T cells (total, 2×10^5 cells/mL). CM (12%, vol/vol) were assessed against NAB-T target cells. Results are expressed as means ± SEM from four experiments. Ep, 5 U/mL added D3, no MoCM except for panel 2. □, 21% O₂; ▨, 5% O₂.

CFU-GM was observed, which increased to 142 ± 7 CFU-GM upon the addition of 1% MoCM. CM from T cell-M ϕ mixtures under 21% O₂ gave rise to 6 ± 1 CFU-GM, whereas CM from a T cell/M ϕ mixture under 5% O₂ yielded 21 ± 3 CFU-GM.

Effects of antioxidants on BFU-E growth at 21% and 5% O₂. To determine whether the increased colony-forming ability of bone marrow MNC at 5% O₂ reflects the protection of erythroid progenitors from accessory cell-derived oxidant injury at 21% O₂, we cultured marrow target cells containing T cells and M ϕ in the presence of three separate antioxidants: reduced glutathione, an intracellular antioxidant, at a concentration range of 0.1 μ mol/L to 10 mmol/L; superoxide dismutase, a scavenger for superoxide radicals, at a concentration range of 0.1 to 1,000 μ g/mL; and catalase, which reacts with H₂O₂, at a concentration range of 1 to 100,000 U/mL. Cultures were established at both 21% and 5% O₂. As shown in Figs 4A, B, and C, marrow BFU-E grown in the presence of varying concentrations of the three antioxidants failed to demonstrate augmented growth at 21% O₂, which suggests that the observed augmentation in BFU-E grown from marrow MNC at 5% O₂ in the absence of antioxidants did not arise as a consequence of reduced O₂ toxicity. Moreover, augmentation in BFU-E was maintained at 5% O₂ relative to 21% O₂ in the presence of each of these antioxidants.

Fig 4. Effect of antioxidants on erythroid progenitors (BFU-E) grown from unseparated bone marrow MNC at 5% and 21% O₂. Results are expressed as means $\pm$ SEM of the number of BFU-E per 1.5×10^5 cells plated from three separate experiments. (A) Reduced glutathione. (B) Superoxide dismutase. (C) Catalase.

Sensitivity of BFU-E to BPA under 5% O₂. Although the aforementioned results indicate that M ϕ and T cells together mediate augmentation of BFU-E under 5% O₂, we next assessed whether low oxygen tensions may additionally alter the sensitivity of early erythroid marrow progenitors to BPA. Using nonadherent, T cell-depleted marrow target cells, we assessed the differential sensitivity of BFU-E cultured at 5% O₂ or 21% O₂ to varying concentrations of exogenous BPA (MoCM). Figure 5A shows the results of a representative experiment of dose-response curves measured at 5% and 21% O₂ as a function of MoCM concentration. The dose-response curves at the two O₂ concentrations were virtually identical. The results of three additional experiments confirmed this observation (data not shown). Any change in the sensitivity of BFU-E under 5% O₂ to exogenous BPA would be reflected in augmented colony growth at low MoCM concentrations, especially since similar number of BFU-E were obtained at 5% and 21% O₂ in the absence of MoCM. However, our results indicate that the percent change in BFU-E growth for 1% to 10% MoCM fluctuates around zero ($n = 4$) (Fig 5B). These results suggest that

marrow BFU-E cultured in the presence of either 5% O₂ or 21% O₂ demonstrate similar sensitivity to exogenous BPA.

DISCUSSION

We have investigated the effects of physiological O₂ tensions (5% O₂) on human marrow BFU-E growth. Our results demonstrate augmentation in BFU-E when marrow MNC are grown under 5% O₂. BFU-E enhancement appears to be mediated by M ϕ and T cells, since the removal of either M ϕ , T cells, or both abolished BFU-E augmentation at 5% O₂. The addition of 10% to 20% M ϕ or 5% to 40% T cells to autologous nonadherent T cell-depleted marrow target cells failed to restore BFU-E augmentation at 5% O₂. However, the readdition of M ϕ to nonadherent MNC, T cells to T cell-depleted MNC, or both T cells and M ϕ to nonadherent T cell-depleted target cells restored BFU-E augmentation under 5% O₂. CM prepared at 5% O₂ from a mixture of M ϕ and T cells demonstrated potent BPA activity, whereas little or no BPA activity was detected with CM from a mixture of T cells and M ϕ at 21% O₂ or from T cells or M ϕ alone under either 5% or 21% O₂. No BFU-E augmentation was observed

Fig 5. Sensitivity of erythroid progenitor cells (BFU-E) grown under either 5% O₂ or 21% O₂ to exogenous BPA derived from MoCM. (A) BPA dose-response curves under 5% and 21% O₂. BPA dose-response curves were determined using nonadherent T cell-depleted (NAB-T) marrow target cells and 0% to 10% MoCM as a source of exogenous BPA. Bone marrow cells were grown under either 21% O₂ or 5% O₂ and were obtained from the same donor. Results are expressed as means $\pm$ SEM from triplicate cultures. (B) Percent augmentation under 5% O₂ as a function of BPA concentration ($n = 4$). Note that the percent change fluctuates around 0.

under 21% O₂ when BFU-E were cultured in the presence of a variety of antioxidants. The sensitivity of BFU-E grown from nonadherent T cell-depleted marrow target cells to exogenous BPA was virtually identical at 5% O₂ and 21% O₂. These results suggest that T cells and M ϕ collaborate to produce BPA and augment human marrow erythropoiesis under 5% O₂.

Although CFU-GM growth was augmented at 5% O₂ relative to 21% O₂, it was not mediated by T cells and M ϕ , since the removal of either T cells or M ϕ did not abolish the CFU-GM augmentation. In addition, CM prepared from T cell/M ϕ mixtures at 5% O₂ demonstrated little CSF activity. Enhancement in colony formation by T cells and M ϕ under 5% relative to 21% O₂ is therefore specific for BFU-E.

A reduction in oxygen toxicity under physiological O₂ tensions may contribute to augmented BFU-E growth at 5% O₂. Rich and Kubanek have observed augmented growth of murine CFU-E and BFU-E under reduced O₂ tensions and have demonstrated that part of this increase in erythropoiesis can be explained by lowered oxygen toxicity under 5% O₂.⁷ Direct oxygen toxicity affecting erythroid progenitor cells with a consequent impairment of BFU-E expression at 21% O₂ seems unlikely from our experimental results, since BFU-E growth from marrow target cells depleted of both M ϕ and T cells was not augmented under 5% O₂. Impairment of T cell-M ϕ collaboration as a consequence of oxygen toxicity at ambient (21% O₂) concentrations could explain the observed BFU-E augmentation under 5% O₂. If this were the case, we would most likely have observed erythropoietic augmentation with marrow MNC containing M ϕ and T cells in the presence of antioxidants. No such stimulation was observed when BFU-E were cultured in the presence of either reduced glutathione, superoxide dismutase, or catalase, which suggests that reduced O₂ toxicity at lower O₂ tensions does not account for the BFU-E augmentation in the absence of antioxidants at 5% O₂. Moreover, BFU-E augmentation at 5% O₂ relative to 21% O₂ is maintained in the presence of each of the assessed antioxidants, which suggests that the observed augmentation is independent of O₂ toxicity. Finally, Ascensao¹⁷ has shown that oxidant injury to human erythroid progenitor cells can be demonstrated only in the presence of low serum concentrations. In addition, Shulman et al¹⁸ demonstrated oxygen toxicity to human erythroid progenitor cells only in the presence of a superoxide-generating system like xanthine-xanthine oxidase. Since we routinely used 50 μ mol/L 2-mercaptoethanol and 30% FCS in our culture system, the role of O₂ toxicity in mediating erythropoietic augmentation under 5% O₂ may well not be significant.

To our knowledge, this is the first demonstration that the augmented BFU-E growth under low O₂ tensions is mediated directly or via additional accessory cells by both M ϕ and T cells. Several reports in the literature suggest that either T cells, M ϕ , or both are required for BFU-E and CFU-GM proliferation *in vitro* at ambient O₂ tensions.^{12,19-29} However, the uniqueness of our results is that T cells and M ϕ can mediate augmented erythropoiesis by releasing burst-enhancing factors in response to variations in O₂ tensions.

This is an important concept since there is a gradation in O₂ tensions in the circulation, capillaries, in various tissues, and in bone marrow medullary cavities.¹⁻³ Increased erythropoietin production or release is considered the sole mechanism mediating erythropoietic response to low O₂; our results suggest that immunoregulatory mononuclear cells can also sense variations in O₂ tensions by releasing hematopoietic growth-promoting activities. Whether M ϕ in response to variations in O₂ tensions release a factor similar to that described by Bagby et al²⁷ that stimulates BPA production by T cells or whether T cells in response to variations in O₂ tensions stimulate M ϕ either directly or through a soluble mediator²⁰ remains to be elucidated.

There are precedents in the literature for low O₂ tensions affecting specific cellular metabolic activities and the ability of MNC to secrete or respond to purified growth factors. O₂ has been demonstrated to alter activities of several enzymes that require molecular O₂ for activity (eg, cytochrome oxidase and ATPase). Simon et al and Cummisley et al have demonstrated in murine epithelial cells and macrophages that enzyme activities in the glycolytic pathway (eg, pyruvate kinase, phosphofructokinase, and hexokinase) are elevated and those of oxidative phosphorylation (eg, cytochrome oxidase) are depressed under 2% O₂.^{30,31} Knighton et al have recently demonstrated that when cultured under low pO₂ macrophages secrete an active angiogenesis factor that aids wound healing.³² The factor secretion ceased when cells were returned to ambient O₂ tensions; thus in this example, MNC appear to secrete a growth factor in response to low O₂ tensions. Smith et al (personal communication) have demonstrated that proliferative response to the growth hormone IgF1 by IgF1 receptor-positive T leukemia cells is achieved only under 5% O₂. In this example, low O₂ tensions enable the T cells to respond to IgF1.

Monocytes have been reported to release hematopoietic growth factors under reduced O₂ tensions in murine and human systems. Rich et al have demonstrated that murine monocytes, when cultured in hydrophobic Teflon foils, can be induced to release Ep, BPA, and CSF-GM at 21% O₂ and that the release of Ep can be augmented at 5% O₂.^{33,34} It is unlikely that the erythroid augmentation observed at 5% O₂ in our experiments is mediated by Ep, since no BFU-E were formed at 5% O₂ in the absence of Ep and marrow BFU-E augmentation is maintained even at high concentrations of Ep (Fig 2). Broxmeyer⁸ has also observed, in a preliminary report, an increased release of CSF-GM from peripheral blood M ϕ under low O₂ tensions, which suggests a role for accessory cells in mediating granulopoietic augmentation under 5% O₂.

Although M ϕ and T cells augment BFU-E at 5% O₂ by collaborating to produce BPA-like activity, the addition of excess exogenous BPA (MoCM, 1% to 10%) did not abrogate this augmentation. The failure of MoCM to abrogate erythroid augmentation under 5% O₂ suggests a possible heterogeneity in either the progenitor target cell population and/or in the erythroid potentiating responses of T cells and M ϕ . Alternatively, progenitor cells may well be capable of responding to greater amounts of erythroid potentiating

activity than that provided by MoCM. MoCM is prepared from an HTLV-containing leukemic T cell line and undoubtedly contains a mixture of lymphokines in addition to BPA, some of which may suppress erythropoiesis.³⁵ Third, T cells and M ϕ may collaborate at 5% O₂ tensions to release potentiators of erythropoiesis distinct from BPA. Prostaglandin E, which is released by M ϕ and stimulates BFU-E in the presence of T cells, is a possible mediator of augmented BFU-E at 5% O₂.³⁶⁻³⁸ However, in two separate experiments, we have observed that the BFU-E augmentation observed under 5% O₂ is maintained in the presence of up to 10 μ mol/L indomethacin, a potent inhibitor of prostaglandin E release from M ϕ .³⁸ Interleukin 2 (IL2) is another possible T cell-derived lymphokine capable of erythropoietic augmentation under ambient O₂ tensions,³⁹ and it may have a role in mediating the BFU-E response to physiological (5%) O₂ tensions. However, although IL2 can stimulate BFU-E proliferation in the presence of BPA and accessory cells, the role of IL2 in BFU-E proliferation in the absence of accessory cells and BPA is not yet established. Finally, it is possible that a suppressor lymphokine for erythropoiesis is released via a collaborative interaction between T cells and M ϕ at 21% O₂ but not at 5% O₂. We rule out this possibility based on the following observations: (1) The number of BFU-E with CM derived from T cell-M ϕ mixtures at 21% O₂ was not lower than in the presence of CM derived from either T cells or M ϕ alone. (2) The addition of T cell/M ϕ CM (at 21% O₂) to cultures containing MoCM did not reduce BFU-E growth (data not shown), and (3) CM from T cell/M ϕ

mixtures contained little interferon activity (1 to 2 U/mL as measured by radioimmunoassay), either at 5% or 21% O₂.

Broxmeyer has reported increased human marrow CFU-GM growth under 5% O₂ when compared with simultaneous cultures established under 21% O₂.⁸ This augmentation was accompanied by an increased HLA-DR expression on CFU-GM progenitor cells and by an increased number of S-phase progenitor cells. Although any direct effect of altered O₂ tensions on the erythroid progenitor cell independent of T cells and Mo appears unlikely from our data, it is possible that the BPA-like activity released by T cell-M ϕ collaboration under 5% O₂ may induce increased HLA-DR expression on erythroid progenitor cells and may increase the percentage of erythroid progenitor cells in S-phase.

Our data suggest that T cells and M ϕ can respond to variations in O₂ tensions by collaborating, either directly or indirectly, to produce BPA-like activity with a consequent augmentation in erythropoiesis. Although it has been well documented that increased erythropoietin is produced in response to in vivo hypoxic stress,⁴ we speculate that augmentation in the production or release of BPA-like activity from M ϕ and T cells could represent an additional mechanism mediating the response of erythropoiesis to alterations in tissue and marrow oxygen tensions. Preliminary experiments in our laboratory⁴⁰ indicate that the lack of appropriate compensatory polycythemia in some patients with chronic disease and hypoxemia may be, in part, a consequence of impaired progenitor augmentation under reduced oxygen tensions.

T Cell Differentiation Stages Identified by Molecular and Immunologic Analysis of the T Cell Receptor Complex in Childhood Lymphoblastic Leukemia

By Joseph Mirro, Jr, Geoffrey Kitchingman, Frederick G. Behm, Sharon B. Murphy, and Rakesh M. Goorha

T cell differentiation was investigated by determining the relationship of T cell receptor (Ti) gene rearrangement and transcription to the expression of surface and cytoplasmic T3 antigen using blast cells from five children with acute lymphoblastic leukemia of thymic origin. Patterns of monoclonal antibody (MoAb) reactivity indicated that these cases were representative of the three recognized stages (I, II, III) of human thymocyte development. The T3 antigen, which becomes linked to the Ti to form a functional T cell receptor complex on mature thymocytes, was expressed on the cell surface in two cases (stage III). However, in the remaining three cases that were surface T3 negative (stages I and II), large amounts of T3 were identified in the cytoplasm by immunoperoxidase staining and flow cytometry. Leukemic blasts from all five patients showed rear-

ranged genes encoding the β -chain portion of the Ti heterodimer. RNA transcripts of Ti β -chain genes were also evident in lymphoblasts from all five cases, but transcripts coding for the α -chain portion of Ti were found only in cases that expressed T3 on the cell surface. Thus the absence of surface T3 (and presumably Ti) coincides with the absence of Ti α -chain RNA, suggesting that transcription of α -chain genes is a critical regulatory event in the surface expression of the Ti-T3 complex. Leukemic T cells that rearrange and express Ti β -chain genes but lack Ti α -chain messenger RNA (mRNA) may represent a stage of differentiation analogous to pre-B cells, where heavy-chain immunoglobulin (Ig) genes are rearranged and expressed but light-chain Ig genes are not expressed.

©1987 by Grune & Stratton, Inc.

THREE STAGES of T cell ontogeny have been delineated using monoclonal antibodies (MoAbs) to detect the expression of the cell surface antigens T11, T6, T4, T8, and T3. Stage I is characterized by the phenotype T11⁺, T6⁻, T4⁻, T8⁻, T3⁻; stage II by T11⁺, T6⁺, T4⁺, T8⁺, T3⁻; and stage III by T11⁺, T6⁻, T4⁺, T8⁺, T3⁺.¹ A 90-kDa disulfide-linked heterodimer, composed of α and β subunits and termed the T cell antigen receptor Ti, also appears on the surface of stage III T lymphocytes and is responsible for T cell antigen specificity.²⁻⁵ The ability of the Ti molecule to recognize many diverse antigens, like that of the immunoglobulins, resides in the rearrangement of genes encoding specific Ti subunits termed variable (V), diversity (D), joining (J), and constant (C).^{6,7} The Ti heterodimer is physically linked to the T3 molecule to form a functional Ti-T3 complex.^{4,5,8-10}

The development of molecular probes for the Ti α - and β -chain genes has made it possible to examine the sequence of gene activation that accompanies production of a functional T cell receptor.¹¹⁻¹³ Previously others have used immunoglobulin gene probes and MoAbs to lineage-associated surface antigens to dissect B cell differentiation.¹⁴ We rea-

soned that similar analysis of Ti gene rearrangement and transcription with T cell surface antigens, such as T3 and T11, might yield additional insight into the sequence and regulation of T cell differentiation. The correlations identified here for T lymphoblasts are similar to those for normal thymocytes and indicate that T cells contain cytoplasmic T3 antigen and Ti β -chains transcripts very early in ontogeny. Ti α -chain transcripts and presumably the α -chain protein were present only in blast cells with surface T3 antigen, indicating that α -chain transcription is a critical regulatory event in the formation of the Ti-T3 complex. The presence of β -chain messenger RNA (mRNA) in the absence of α -chain mRNA appears to characterize a stage of T cell differentiation analogous to the pre-B stage of B lymphocytes where heavy-chain Ig genes are expressed but light-chain Ig genes are not.

MATERIALS AND METHODS

Patients. From 10⁷ to 10⁸ marrow blast cells (density <1.077 g/cc) were obtained from five children with untreated T cell acute lymphoblastic leukemia (T-ALL). These cases were selected for analysis because they represented the known stages of T cell differentiation as defined by reactivity with MoAbs. Thymocytes were obtained from normal human thymus removed during corrective cardiac surgery. All studies described in this report were performed with approval of the Clinical Trials Committee of St. Jude Children's Research Hospital and with the informed consent of the patients and their parents.

Immunologic studies. Leukemic blast cells from marrow aspirates were studied for expression of cell-surface antigens by a standard indirect immunofluorescence assay that relied on MoAbs in the cluster groups (CD) known to react with T cell-associated antigens¹⁵ (OKT series, Ortho Diagnostics, Raritan, NJ). Isotypic myeloma immunoglobulins (Littion-Bionetics, Charleston, SC), at a concentration equal to the least diluted MoAb, were used as negative controls; samples demonstrating >10% fluorescence with the myeloma immunoglobulins were considered unacceptable.¹⁶

Cryopreserved leukemic cells and normal thymocytes were tested for cytoplasmic antigens by immunoperoxidase staining.¹⁷ Cytoentrifuged cells (1 to 2 × 10⁵ per slide) were fixed in cold acetone (4 °C for three minutes) and were then stained with either Leu-4 (CD-3) or Leu-5b (CD-2) antibody (Becton Dickinson, Mountain View, CA) at a 1:10 dilution (25 °C for 45 minutes) or isotype-matched

myeloma immunoglobulins (negative controls). Leu-4 and Leu-5b were used in these experiments because they are superior to OKT3 and OKT11 in the immunoperoxidase assay. Sequentially, with washing in phosphate-buffered saline (PBS) between steps, an affinity-purified biotinylated horse antimouse IgG (Vector Laboratories, Burlingame, CA) was added (25 °C for 20 minutes), followed by avidin DH: biotinylated horseradish peroxidase H complex (Vector Laboratories) (25 °C for 15 minutes) and, finally, 0.1% diaminobenzidine tetrahydrochloride (DAB; Polysciences, Warrington, PA).¹⁸

Cryopreserved leukemic cells were also analyzed for the presence of cytoplasmic antigens by flow cytometry.¹⁹ Briefly, 5×10^6 cells/mL were treated with lysolecithin (lysophosphatidylcholine; Sigma, St Louis) at a concentration of 5 µg/mL in PBS, pH 7.2, without calcium or magnesium (4 °C for three minutes) to permeabilize cell membranes. Washed cells were stained by a standard immunofluorescence technique using a twofold excess of either Leu-5b, (CD-2), Leu-4 (CD-3) antibody or isotype-matched immunoglobulins and were analyzed with an EPICS flow cytometer with a five-W coherent laser (Coulter, Hialeah, FL).

DNA analysis. High-mol wt DNA was prepared from bone marrow cells as described previously, digested with *Bam*HI, *Eco*RI, or *Xba*I restriction endonuclease, electrophoresed through a 0.8% agarose gel, and transferred to nitrocellulose.²⁰ Blots were probed with nick-translated DNA, with plasmid pB400 (provided by Dr M.J. Owen) used as the source of Ti β -chain DNA.²¹ This probe contains 464 nucleotides of the constant region of $C\beta_1$, and 15 bases of the joining region; it hybridizes well to both the Ti β -chain genes. Filters were washed and exposed to Kodak XAR film in the presence of Dupont Lighting Plus intensifying screens.

Northern hybridization analysis. The cDNA clones containing inserts encoding the human Ti α - and β -chain genes have been described.^{21,22} Inserts containing α - and β -genes were isolated and oligolabeled to specific activities of 7 to 20×10^8 cpm/µg of DNA.²³ Total cellular RNA was prepared from leukemic blast cells or the T cell line HPB-ALL by a guanidinium/cesium chloride procedure.²⁴ RNA was denatured in 50% formamide/2.2 mol/L formaldehyde, electrophoresed in 1% agarose, and transferred to nitrocellulose filters. After hybridization for 24 hours, filters were washed in 0.1 mol saline citrate solution at 50 °C (two washed for 15 minutes).

RESULTS

Characteristics of the patients. The clinical characteristics of these four boys and one girl (Table 1) were entirely consistent with ALL of thymic origin. Leukocyte counts exceeded $100 \times 10^9/L$ in all children with a median of $222 \times 10^9/L$ (range, 111.6 to $651.2 \times 10^9/L$). Four patients had a mediastinal mass. Immunologic evaluation (Table 1) established the T cell origin of the cases, with blast cells from all patients reacting strongly with MoAbs that recognize T11 (CD-2) (median 88%, range 85% to 95%). The MoAb binding patterns indicated that the lymphoblasts in case 1 corresponded with stage I thymocytes, those in cases 2 and 3 corresponded with stage II thymocytes, and those in cases 4 and 5 corresponded with stage III thymocytes (Table 1). Surface T3, by definition, was present only on blasts from stage III patients (cases 4 and 5); however, cryopreserved lymphoblasts from all five patients contained large amounts of T3 within the cytoplasm when examined by immunoperoxidase staining (Table 1 and Fig 1A). Furthermore, a higher percentage of cells from patients 4 and 5 contained cytoplasmic T3 by immunoperoxidase staining than was

evident from surface immunofluorescence testing (Table 1). When normal thymocytes were studied by immunoperoxidase staining, greater than 90% contained cytoplasmic T3 (Fig 1B).

Flow cytometric analysis of cryopreserved lymphoblasts from patient 2, stained by a standard immunofluorescence technique, failed to disclose surface T3; however, when cell membranes were disrupted with lysolecithin and then stained, 38% of the blasts became positive (Fig 2). The lysolecithin treatment did not change the reactivity pattern seen with the myeloma immunoglobulin negative control or that seen with antibodies T11 and Leu-5 (CD-2).

Molecular analysis. Rearrangement of the two genes encoding the Ti β -chain can be analyzed as a unit by *Bam*HI digestion or separately by *Eco*RI ($C\beta_1$) and *Xba*I ($C\beta_2$) digestions. Table 2 summarizes the results of our analysis of the Ti β -chain gene in DNA from each of the five patients. *Bam*HI digestion demonstrated rearranged Ti β -chain genes in blasts from four of our patients (cases 2 through 5). Examination of the DNA from patient 1 by *Eco*RI and *Xba*I digestions revealed that one $C\beta_1$ gene was rearranged and one was deleted, while one $C\beta_2$ gene was rearranged and one remained in the germ-line configuration (Table 2). Blast cells from patient 2 showed deletion of both $C\beta_1$ genes and rearrangement of both $C\beta_2$ genes. In patient 3 the rearrangements involved only one allele of the $C\beta_1$ gene, and in patient 5 there was deletion of the $C\beta_1$ gene and rearrangement of one of the $C\beta_2$ genes. Patient 4 had an unexpected pattern of β -gene rearrangement. The *Bam*HI digestion pattern indicated that both gene clusters had rearrangements. However, analyses with *Xba*I and *Eco*RI indicated that both rearrangements were in the $C\beta_2$ genes with persistence of the $C\beta_1$ genes in an apparent germ-line configuration. One possible explanation for this finding is the presence of a V region cluster downstream of the $C\beta_2$ constant region.²⁵

Total cytoplasmic RNA was analyzed by the Northern blot technique to determine if the rearranged Ti β -chain genes were being transcribed (Fig 3, Table 2). RNA from patients 1 through 3 and 5 (sufficient cells were not available

Fig 1. (A) Reactivity of Leu-4 (CD-3) antibody with leukemic blast cells from patient 2, detected by the immunoperoxidase staining technique. (B) Reactivity of Leu-4 antibody with normal thymocytes detected by the immunoperoxidase staining technique.

from patient 4) contained a 1.3-kilobase (kb) transcript that hybridized to the probe for the β -chain gene (Fig 3). The size of this transcript is similar to that in HPB-ALL cells (stage III, surface T3 positive) producing the protein; hence, the Ti β -chain was probably being synthesized in the blast cells of our patients (data not shown for patient 2). When analyzed with the α -chain probe, total RNA from patients 1 through 3 (surface T3 negative but cytoplasmic T3 positive) lacked transcripts of the α -chain gene. By contrast, RNA from patient 5 (surface T3 positive) included a 1.4-kb band that hybridized to the probe (Fig 3). The similarity of this 1.4-kb band to mRNA transcripts in HPB-ALL cells (surface T3 positive) suggests that functional Ti α -chain was being synthesized. Thus lymphoblasts from all of the patients we studied contained RNA that hybridized to the Ti β -chain gene probe, but only lymphoblasts from patient 5 (surface T3 positive) contained RNA that hybridized to the Ti α -chain probe.

DISCUSSION

Our results demonstrate discordance between the surface and cytoplasmic expression of T3 antigen in leukemic cells. Cytoplasmic presence of T3 antigen was detected in all MoAb-defined stages of development, but surface T3 was present only in stage III. Link et al¹⁸ have also described cytoplasmic T3 expression without surface T3 expression in 16 of 17 cases of T cell ALL and T cell lymphoblastic lymphoma. Additionally we found that greater than 90% of the normal thymic cells contain cytoplasmic T3, whereas a lower percentage of these cells show surface T3. The results with normal thymocytes strongly suggest that cytoplasmic T3 positive, surface T3 negative leukemic cells correspond to a normal stage in T cell differentiation.

We also examined the relationship of Ti gene rearrangement and/or their transcription to cytoplasmic and surface T3 expression in T cell ontogeny. Similar to other investigators,^{2,6,7,26} we found Ti β -chain gene rearrangements in leukemic cells representing all three stages of thymocyte development. We could not examine DNA for rearrangements of Ti α -chain genes, as probes suitable for completely examining the full length of this estimated 50-kb gene are not yet available.²⁷ Lacking a pan-Ti antibody, we examined total RNA from four cases for the presence of α - and β -chain transcripts in an effort to clarify the differential expression of genes encoding the T cell receptor in lymphoblasts. This analysis indicated that transcripts of the Ti β -chain gene are present even in the earliest stage of T cell differentiation detectable by MoAbs. In patients with blasts containing cytoplasmic T3 but not surface T3, we could not demonstrate Ti α -chain gene transcripts. However, in surface T3-positive lymphoblasts, both β - and α -chain transcripts were present. A similarly ordered transcription of α and β Ti genes has been seen during intrathymic ontogeny.^{28,29} The findings we report expand our understanding of thymocyte development. T cells containing Ti β mRNA and presumably expressing

Fig 3. Northern blot analysis of total cellular RNA to identify transcripts of Ti β - and α -chain genes. β -Chain gene: lane 1 contains control RNA from HPB-ALL cells (surface T3⁺), lane 2 contains RNA from patient 1 (cytoplasmic T3⁺, surface T3⁻), lane 3 contains RNA from patient 3 (cytoplasmic T3⁺, surface T3⁻), and lane 4 contains RNA from patient 5 (surface T3⁺). α -Chain gene: lane 1 contains RNA from patient 5, lane 2 contains control RNA from HPB-ALL cells, lane 3 contains RNA from patient 1, and lane 4 contains RNA from patient 3. No α -chain gene hybridizing bands are evident in lanes 3 and 4 (patients 1 and 3).

the β -chain protein but lacking Ti α mRNA and protein would appear to be analogous to pre-B cells where the heavy chain Ig gene protein but not the light-chain Ig gene protein is expressed.³⁰ These pre-T cells would include both stage I and II thymocytes in the Reinherz et al schema.¹

Taken together, our results on the cytoplasmic and surface expression of T3 and transcription of α and β Ti genes suggest that transcription of the α -chain gene is a critical regulatory event in Ti formation and transport of the T3 antigen to the cell surface. It is possible that in lymphoblasts the Ti α -chain genes are rearranged, but no mRNA is produced because of nonproductive somatic rearrangements, similar to the situation with immunoglobulin genes. The differentiation sequence we have identified in leukemia appears identical to that occurring in normal thymocytes.^{28,29}

Leukemic blast cells from all patients and most thymocytes expressed surface T11 (CD-2), contained rearranged and transcribed Ti β -chain genes, and had cytoplasmic T3. Since this manuscript was submitted, results similar to these have been reported by Furley et al, and these investigators have identified thymocytes with cytoplasmic T3 without Ti β -chain rearrangement.³¹ Taken together, our results and those of Furley et al indicate that the hierarchy of T cell gene rearrangements and expression (T11, T3, Ti, and others) is much more complex than first thought and will require further combined immunologic and molecular studies with thymocytes and leukemic T cells to be fully elucidated.

ACKNOWLEDGMENT

We wish to thank Drs M.J. Owen and T. Mak for their kind gifts of gene probes and J. Gilbert for assistance in writing the manuscript.

The Influence In Vivo of Murine Colony-Stimulating Factor-1 on Myeloid Progenitor Cells in Mice Recovering From Sublethal Dosages of Cyclophosphamide

By Hal E. Broxmeyer, Douglas E. Williams, Scott Cooper, Abdul Waheed, and Richard K. Shadduck

Pure murine colony-stimulating factor-1 (CSF-1) was assessed for its effects in vivo in mice pretreated seven days earlier with a sublethal dosage of cyclophosphamide. The multipotential (CFU-GEMM), erythroid (BFU-E), and granulocyte-macrophage (CFU-GM) progenitor cells in these mice were in a slowly cycling or noncycling state. Intravenous administration of 20,000 units of CSF-1 to these mice stimulated the hematopoietic progenitors into a rapidly cycling state in the marrow and spleen within three hours. Significant increases in absolute numbers of marrow and spleen CFU-GM and spleen BFU-E and CFU-GEMM were also detected. No endotoxin was detected in the CSF-1 preparation by *Limulus* lysate assay, and treatment

of CSF-1 at 100 °C for 20 to 30 minutes completely inactivated the in vitro and in vivo stimulating effects. The effects of CSF-1 were not mimicked by the in vivo administration of 0.1 to 10 ng *Escherichia coli* lipopolysaccharide. These results suggest that the effects of CSF-1 in vivo were not due to contaminating endotoxin or to a nonspecific protein effect. CSF-1 did not enhance colony formation by BFU-E or stimulate colony formation by CFU-GEMM in vitro, thus suggesting that at least some of the effects of CSF-1 noted in vivo are probably indirect and mediated by accessory cells.

COLONY-STIMULATING FACTOR-1 (CSF-1), macrophage CSF, is one of a group of CSFs defined operationally by their ability to stimulate colony formation by hematopoietic progenitor cells in semisolid culture medium,^{1,2} although it is apparent that CSFs can also influence the functional capacity of more mature cells.³⁻⁵ CSF-1 from human and murine sources have been purified to homogeneity,⁶⁻⁹ and the complementary DNA for CSF-1 derived from a human cell line has been cloned and expressed.¹⁰ Information is available on the production,¹¹ receptor-binding capability,¹²⁻¹⁹ and actions in vitro of CSF-1,³⁻⁵ but there is a paucity of information on the effects of CSF-1 in vivo²⁰⁻²² and evidence that CSF-1 may function in vivo is mainly indirect.

The present studies were designed to evaluate the short-term effects in vivo of a single injection of endotoxin-free purified murine CSF-1 on myelopoiesis in mice pretreated with a sublethal dosage of cyclophosphamide. It was reasoned that it might be easier to detect an effect of exogenously administered CSF-1 in mice in which the proliferative status of hematopoietic progenitor cells was suppressed during the overbound phase of myelopoiesis resulting from the cytotoxic effects of cyclophosphamide. This model allowed the detection of a significant proliferative effect of CSF-1 in vivo on bone marrow granulocyte-macrophage (CFU-GM) and macrophage (CFU-M) progenitor cells and on spleen CFU-GM, multipotential (CFU-GEMM), and erythroid (BFU-E) progenitor cells.

MATERIALS AND METHODS

Mice. (C57B1/6 × DBA/2) F₁ (BDF₁) mice, 6 to 8 weeks old, were purchased from Cumberland View Farms (Clinton, TN).

Molecules. L cell CSF (CSF-1) was produced by the growth of murine L cells in serum-free CMRL 1066 medium.⁷ A 10-L pool of conditioned medium was purified by affinity chromatography⁸ and had a specific activity of 2.3×10^7 U/mg of protein when assayed by the in vitro growth of murine bone marrow colonies. This material was subjected to sucrose gradient centrifugation as a means of removing any potential endotoxin.²³ After centrifugation at 100,000 g for 18 hours, the upper third of the sucrose gradient was aspirated and diluted in 0.1 mmol/L Tris-HCL containing 0.3% polyethylene glycol 4000 as a stabilizing agent. A control solution was prepared

using the upper third of a sucrose gradient that did not contain CSF. The CSF-1 was injected in a volume of 0.2 mL and had no detectable endotoxin as determined by the *Limulus* lysate assay (Sigma Chemical Co, St Louis), which can detect endotoxin concentrations down to 0.5 ng/mL. Cyclophosphamide (Cytosan, Bristol Myers Oncology Division, Syracuse, NY) was diluted in sterile pyrogen-free water prior to intraperitoneal (IP) injection.

Cell preparation. Both femurs were excised and the shafts cleaned of residual muscle tissue. The ends of each bone were then carefully cut off without exposing the marrow cavity. To wash cells out of the femurs, a sterile 27-gauge needle was forced into the upper and lower end of the femur to allow fluid to pass through the bone. Cells were then flushed from each femur by passing 5 mL of ice cold McCoy's 5A medium (GIBCO, Grand Island, NY) through each bone. Medium was forced through both ends of each bone to ensure that the maximum number of cells was removed from each bone shaft. Cells from two femurs per animal were pooled and single-cell suspensions made by passage through a 23-gauge needle. Spleens were removed and placed in 60 × 15-mm tissue culture dishes containing 10 mL of McCoy's 5A medium. Spleens were forced through a sterile wire mesh screen several times using the sterile barrel of a 10 mL syringe. Single-cell suspensions were made as for marrow cells by passing cells through a 23-gauge needle. The viability of suspended marrow and spleen cells was routinely >98%.

Mice were injected IP with 200 mg cyclophosphamide/kg body weight. Seven days later the mice were injected IV with control diluent, 20,000 units purified CSF-1, 20,000 units of CSF-1 that had been heated at 100 °C for 20 to 30 minutes, or 10, 1, or 0.1 ng *E. coli*/lipopolysaccharide (LPS). The mice were sacrificed three hours later. For control diluent or CSF-1, results are the averages of 15 mice each (in a total of five experiments). For heat-treated CSF-1, results are the averages of 11 mice (in a total of four experiments), and for LPS the results are the averages of six mice each (in a total of two experiments).

*The percent change from control diluent (% Δ) is given in parenthesis.

†NS, not scored. Control colony numbers were too low to use.

‡Significant percent increase from control diluent, P at least $< .05$.

§Significant percent decrease from control diluent, P at least $< .05$.

Analysis of hematopoietic progenitor cells in vitro. The assay for CFU-GM was performed as described²⁴ by using pokeweed mitogen mouse spleen cell conditioned medium (PWMSCM) as a source of CSF.²⁴ Bone marrow and spleen cells from cyclophosphamide-treated mice were plated respectively at 2×10^5 and 2.5×10^4 cells/mL in 0.3% agar culture medium (Difco Laboratories, Detroit) that included McCoy's 5A medium supplemented with essential and nonessential amino acids, glutamine, serine, asparagine, and sodium pyruvate (GIBCO) with 10% prescreened heat-inactivated (56 °C for one-half hour) fetal bovine serum (Hyclone, Logan, UT). Colonies (>50 cells/aggregate) were scored after seven days of incubation. For colony morphology, agar cultures were overlaid with 1 mL of 0.5% glutaraldehyde (Sigma) in 0.1 mol/L phosphate buffer. After six minutes, the glutaraldehyde was removed, and 2 mL absolute methanol was added to the plates. After the methanol evaporated (12 to 18 hours) the fixed cultures were submerged in distilled water. After rehydration, the agar pellicles were floated onto clean glass slides and allowed to dry. For identification of colonies containing granulocytes and monocytes/macrophages, the colonies were stained for 45 minutes with α -naphthyl acetate esterase (Sigma Kit #90-A1) and counterstained with Mayer's hematoxylin for ten minutes. The slides were washed, dried at room temperature, mounted (Permount, Fisher, St Louis) and scored at 400 $\times$. Monocytes/macrophages were enumerated based on their morphology and the characteristic black cytoplasmic granulation. Granulocytes were nonspecific esterase-negative and had characteristic nuclear morphology.

The assay for BFU-E-2 was plated at 1×10^5 cells/mL for marrow and 2.5×10^4 cells/mL for spleen from cyclophosphamide-treated mice in a 1-mL mixture of Iscove's modified Dulbecco's medium (GIBCO), 0.8% methylcellulose, 30% prescreened fetal bovine serum (Hyclone), 5×10^{-5} mol/L 2-mercaptoethanol, 1 unit of erythropoietin (Hyclone), and 0.1 mmol/L hemin (Eastman Kodak, Rochester, NY). Hemin increases colony formation by BFU-E and CFU-GEMM.²⁵ BFU-E-1 and CFU-GEMM assays were set up as for BFU-E-2 except that 1% vol/vol PWMSCM was added and colonies were scored from the same plates. Cells were plated at 1.0×10^5 cells/mL for bone marrow and 5×10^3 to 2.5×10^4 cells/mL for spleen BFU-E-1 and CFU-GEMM assays. BFU-E-2, BFU-E-1, and CFU-GEMM assays were scored after six to seven days of incubation. The terms BFU-E-2 and BFU-E-1 are operational only because the colonies derived from BFU-E-1 were much larger than those derived from BFU-E-2. It is possible that BFU-E-1 may represent a more immature progenitor than BFU-E-2, although this has not been proved.

Cells were incubated in a humidified environment at lowered (5%) oxygen tension. Low oxygen tension was maintained using an Oxyreducer (Reming Bioinstruments, Rochester, NY) since lowered oxygen tension increases the incidence of colonies derived from hematopoietic progenitor cells.²⁶

Cycle status of hematopoietic progenitor cells. To estimate the proportion of progenitors in DNA synthesis (S-phase), cells were treated with either McCoy's medium or 50 μ Ci tritiated thymidine (³HTdR, New England Nuclear, Boston; specific activity, 20 Ci/mmol). After a 20-minute incubation at 37 °C, the cells were washed once in a buffer containing ice cold thymidine (2,000 μ g), twice more in McCoy's medium, and then plated into the CFU-GM, BFU-E, and CFU-GEMM assays. The reduction in the number of colonies after exposure of the cells to ³HTdR compared with the control (McCoy's medium) estimates the proportion of progenitor cells in cycle just prior to the assay for colony formation. The results are given as the percentage of cells in S-phase. A negative number means that more colonies formed after the cells were exposed to ³HTdR than after the cells were exposed to McCoy's medium. In some select cases, cells were also exposed to 500 μ g thymidine or 50

μ Ci ³HTdR plus 500 μ g thymidine as controls for the S-phase specificity of the treatments. In all cases, the numbers of colonies formed were statistically similar whether the cells were exposed to McCoy's medium, thymidine, or ³HTdR plus thymidine. The percentage of cells in S-phase was based on control colony counts from cells pulsed with McCoy's medium that ranged from 50 to 185, 18 to 37, 15 to 41, and 14 to 45, respectively, for the CFU-GM, BFU-E-2, BFU-E-1, and CFU-GEMM assays.

Experimental protocols. The details of these are described in Results and in the tables. The numbers of mice used are given in the table legends. After sacrifice, the marrow from the two femurs of each mouse was pooled. This marrow and the spleen of each mouse were assayed separately. Cells from different mice were not pooled.

Statistical analysis. Three plates were scored for each CFU-GM sample, and two plates were scored for each BFU-E-2 or BFU-E-1/CFU-GEMM sample. The results are expressed as the mean $\pm$ 1 SEM, and these are derived from the averages of the colony counts from each of the individual mice within a group. The probability of significant differences between groups or samples was determined with the use of Student's *t* test.

RESULTS

Influence of CSF-1 and Escherichia coli lipopolysaccharide in mice pretreated with cyclophosphamide. In preliminary experiments we noted that the cycling status of myeloid progenitor cells was significantly decreased in the bone marrows and spleens removed from mice seven days after IP administration of cyclophosphamide (200 mg/kg body weight) when compared with cells from untreated mice (data not shown). Cyclophosphamide-pretreated mice were thus used to evaluate the potential proliferative effects of CSF-1 in vivo on myeloid progenitors. The mice were injected IP with 200 mg cyclophosphamide followed by a second intravenous (IV) injection seven days later with control diluent, 20,000 units CSF-1, 20,000 units CSF-1 that had been treated at 100 °C for 20 to 30 minutes, or with 0.1 to 10 ng *E. coli* lipopolysaccharide and sacrificed three hours later. The results for the averages of two to five separate experiments are shown in Table 1. In five experiments, CSF-1 had no significant effect on nucleated marrow or spleen cells but significantly increased the absolute numbers of marrow CFU-GM and splenic CFU-GM, BFU-E-2, and CFU-GEMM. CSF-1 also significantly increased the percentage of marrow CFU-GM and splenic CFU-GM, BFU-E-2, BFU-E-1, and CFU-GEMM in cycle. The numbers of marrow BFU-E and CFU-GEMM were too low to evaluate. The increase in cycling CFU-GM was apparent for granulocyte and granulocyte-macrophage progenitors as well as for macrophage progenitors (Table 2). Control diluent had no effects on any of the parameters evaluated that were significantly different from that of sterile pyrogen-free saline (data not shown).

Heat-treated CSF-1 and *E. coli* lipopolysaccharide were used as controls. The effect of heating CSF-1 in vitro at 100 °C for 5, 10, and 20 minutes was assessed on the activity of CSF-1 in vitro. Fifty units of untreated CSF-1 stimulated 101 ± 7 colonies and 203 ± 17 colonies plus clusters per 7.5×10^4 bone marrow cells from untreated mice. After heat treatment of CSF-1, colony, and colony plus cluster, the numbers were reduced to 6 ± 1 and 44 ± 1 , 0 and 2 ± 1 , and 0

The mice were injected IP with 200 mg Cytoxan/kg. Seven days later the mice were injected IV with 20,000 units purified CSF-1, and the mice were sacrificed three hours later. Results shown are for three mice each receiving CSF-1 in vivo. The numbers in parentheses designate the percent change from control (%Δ).

Abbreviations: G, granulocyte; M, macrophage; GM, granulocyte-macrophage.

*Significant percent change from control, *P* at least <.05.

and 0 respectively for preparations of CSF-1 heat-treated for 5, 10, and 20 minutes. In another experiment, CSF-1 stimulated 33 ± 2 colonies and 114 ± 7 colonies plus clusters in vitro, whereas CSF-1 heat-treated at 100 °C for 30 minutes stimulated no colonies and 1.3 ± 0.7 clusters. In each of these experiments the background growth in the absence of CSF-1 was <2 small clusters. Based on this information, CSF-1 was treated at 100 °C for 20 minutes (two experiments) or for 30 minutes (two experiments) and compared with untreated CSF-1 for its effects in vivo (Table 1). Heat-treating the CSF-1 inactivated its effects in vivo. The administration of 0.1, 1.0, or 10 ng *E coli* lipopolysaccharide to mice in vivo (Table 1) had no significant enhancing effect on myelopoiesis and in some cases resulted in significant decreases.

In two experiments the marrow and splenic morphology was evaluated. The percentage of marrow cells from mice treated with control diluent was 5% to 8% myeloblasts and promyelocytes, 66.5% to 73% myelocytes, 12.5% to 13.5% metamyelocytes and bands, 0.5% to 1.5% polymorphonuclear cells (PMN), 4% to 5% monocytes, 2.5% to 4%

lymphocytes, and 0.5% to 2.5% nucleated erythroid cells. The percentage of splenic cells from mice treated with control diluent was 7% to 8.5% myeloblasts and promyelocytes, 29% to 31% myelocytes, 19% to 21.5% metamyelocytes and bands, 9.5% to 12.5% PMN, 2.5% to 4% monocytes, 18% to 21% lymphocytes, and 5.5% to 10% nucleated erythroid cells. These differentials were not significantly changed by administration to the cyclophosphamide-pre-treated mice of CSF-1, heat-treated CSF-1, or 0.1, 1, or 10 ng *E coli* lipopolysaccharide.

Influence of CSF-1 in vitro. The effects of CSF-1 on erythroid and multipotential progenitors was of interest, since we could not detect burst-promoting activity (BPA) or mixed colony (CFU-GEMM) activity in the CSF-1 preparation during assay in vitro. At higher concentrations, CSF-1 decreased colony formation by BFU-E (Table 3).

DISCUSSION

Purified murine CSF-1 that is essentially free of endotoxin (<0.1 ng/injection) has significant stimulating effects on

Table 3. Influence of Pure Murine CSF-1 and PWMSCM on Colony Formation by Murine Marrow BFU-E and CFU-GEMM

marrow and splenic hematopoietic progenitor cells when administered to mice seven days after injection with a sublethal dose of cyclophosphamide. Within three hours of the injection of CSF-1 into mice, the CFU-GEMM, BFU-E, and CFU-GM were induced from a slowly cycling or noncycling state into a rapidly cycling state. Additionally, significant stimulating effects were detected on absolute numbers of marrow and spleen CFU-GM and spleen BFU-E and CFU-GEMM. At this time we did not detect a significant effect on the total nucleated marrow, spleen, or peripheral blood counts or differentials (data not shown). Of interest and potential relevance is the fact that the effects of CSF-1 in vivo were more evident on induction of cycling of progenitors than on changes in progenitor cell numbers. We chose to evaluate the mice three hours after CSF-1 administration because CSF-1 can induce the release in vitro of prostaglandin E,²⁷ acidic isoferritins,⁴ interferon- α ,^{28,29} and tumor necrosis factor²⁹ from monocytes/macrophages and these molecules have suppressive effects in vitro for myeloid progenitor cells. The CSF-1-induced release of these suppressor molecules is usually first detected 12 to 24 hours after the addition of CSF-1 to the cell cultures. It was hoped that by assessing mice within three hours after the administration of CSF-1 in vivo we might obviate the potential CSF-1 induction of suppressor molecules, which might have masked the stimulating effects of CSF-1.

Since endotoxin was not detected in our preparation of CSF-1, at least within the limits of the *Limulus* lysate assay, it does not appear likely that the effects of CSF-1 in vivo are

due to contaminating endotoxin. This belief is further supported by our studies demonstrating that treatment of CSF-1 at 100 °C for 20 to 30 minutes inactivated its stimulating capacity both in vitro and in vivo. This treatment would not have inactivated endotoxin.³⁰ Moreover, the administration of 0.1 to 10 ng *E coli* lipopolysaccharide to these mice did not mimic the effects of CSF-1. The studies with heat-inactivated CSF-1 were also important as controls for the potential nonspecific stimulating effects of proteins in general.

It is not possible to conclude from these studies whether the effects of CSF-1 in vivo are direct ones on the hematopoietic progenitor cells in the marrow and spleen, whether these effects are mediated through an action on accessory cells present in the blood, marrow, or spleen, or whether the actions are both direct and indirect. Although CSF-1 can stimulate colony formation by granulocytes, granulocytes plus macrophages, and macrophages in vitro from an unseparated population of marrow cells,^{31,26} we did not detect BPA or multipotential (CFU-GEMM) activities in vitro with our preparation of CSF-1. CSF-1 can induce the elaboration of other species of CSF from cells in vitro,^{29,32,33} and it is probable that at least some of the effects noted in vivo are mediated through the induced release by CSF-1 of other growth factors for hematopoietic progenitor cells.

ACKNOWLEDGMENT

We wish to thank Shirley Duke and Stephanie Moore for typing the manuscript.

Monoclonal Anti-Light Chain Idiotypic as a Tumor-Specific Probe for Human Neoplastic B Lymphocytes

By M. Wraitham, A.L. Tutt, M.J. Glennie, T.J. Hamblin, G.T. Stevenson, and F.K. Stevenson

Tumor cells from patients with B cell neoplasms often secrete small amounts of free monoclonal light chains that can be found in the urine. Such tumor-derived light chains of the λ type from a patient with typical chronic lymphocytic leukemia have been used to raise mouse monoclonal antibodies (MoAbs). A hybridoma-secreting antibody that recognized the idiotypic λ chain but not normal λ chains by a preliminary screen but which also reacted with idiotypic IgM from the patient's tumor cells was selected. This MoAb in fact recognized 1 in 20×10^3 molecules of pooled normal λ chains, thus establishing its specificity for a private idiotypic determinant. It failed to give a detectable reaction with normal IgM, normal serum, or a panel of IgM paraproteins. The antibody bound to the patient's neoplas-

tic B cells but not to normal tonsillar cells. The site of binding of the antibody to idiotypic IgM is clearly separate from that of another MoAb specific for idiotypic determinants on heavy plus light chains, since the two showed additive binding curves. The determinant also appeared to be less available in dimeric λ chains than in monomeric λ chains or in idiotypic IgM. Antibodies to idiotypic determinants on light chains show some technical advantages and should be useful for monitoring and possibly treating B cell tumors, either alone or together with the more conventional anti-idiotypic antibodies that usually recognize the heavy and light chain combination.

THE IDIOTYPIC determinants of the surface immunoglobulin (Ig) of neoplastic B lymphocytes represent a molecularly defined tumor-associated antigen.¹ Antibodies specific for these determinants have been used for treatment of human lymphoma with some indication of success, although difficulties remain.^{2,3} Monitoring of disease with anti-idiotypic, however, either by identification of tumor cells or by assay of free serum idiotype, presents few problems.^{4,5}

Nevertheless, difficulty in raising such antibodies has prevented widespread use by clinicians, since idiotypic Ig for immunization must first be obtained from the tumor cells, perhaps from a small biopsy, either by enzyme digestion⁶ or by rescue hybridization,⁷ neither of which is a routine procedure. The use of impure immunogen such as tumor cells or membrane preparations, although possible, yields only a small proportion of anti-idiotypic hybridomas from which to select. The use of an alternative source of immunogen, such as the monoclonal light chain derived from tumor cells and found in urine, therefore could represent a simplification of the approach.

In a study of patients with non-Hodgkin's lymphoma, 23/24 patients had tumor cells that secreted free monotypic light chains.⁵ In a separate investigation of random urine samples from patients with B cell disease, about 50% showed monoclonal light chain by sensitive isoelectric focusing.⁸ Presumably the level of the urinary light chain depends partly on tumor load. Such light chains can be prepared by simple immunosorption methods and have been used previously to raise polyclonal antisera for four patients with chronic lymphocytic leukemia (CLL).⁹ One notable finding was that these four antisera, rendered specific for idiotype by absorption, recognized the cell surface IgM on tumor cells from the original patients. The finding was unexpected, since in the reciprocal situation anti-idiotypic raised against combined (heavy plus light chain) idiotype usually does not recognize free light chain.¹⁰

To analyze more critically whether the same antibody could recognize both free and combined light chain idiotype, we have raised a monoclonal antibody (MoAb) with this dual recognition. We have also compared it with a conventional anti-idiotypic antibody raised against idiotypic IgM from the same patient.

MATERIALS AND METHODS

Patient and Cell Preparation

The male patient LP, aged 50 years, presented with typical CLL with a WBC of $50 \times 10^9/L$ consisting of >95% neoplastic B cells that expressed IgM and IgD, both with the λ light chain, on the surface with no detectable intracellular Ig. A bone marrow sample also showed heavy infiltration with tumor cells, >90% expressing IgMD λ . Serum immunoglobulins were at the low end of the normal range, and no paraprotein was detected on routine electrophoresis. Cells were prepared from peripheral blood and were usually frozen in a controlled cell freezer unit for subsequent investigation.⁹ Urine was collected as 24-hour samples directly into bottles containing 5 mL toluene as preservative.

Urinary Light Chain

A sample of concentrated ($\times 100$) urine was analyzed by isoelectric focusing (IEF) with immunofixation as described.⁸ Preparation of the identified λ chain was by sequential immunosorption.⁹ Briefly, urine (500 mL) was passed through a series of 10-mL columns consisting of Sepharose 4B-CL linked to: (1) normal sheep IgG to remove nonspecific adherent material; (2) sheep anti- κ to remove κ light chains; and (3) sheep anti- λ to bind the λ chains. Elution of the last column with 0.5 mol/L NH_4OH -1.0 mol/L KSCN, followed by dialysis into cold 0.1 mol/L Tris-HCl-1 mol/L NaCl to 0.2% NaN_3 , pH 8, isolated the relevant light chain. Any sheep protein detached from the immunosorbent during elution was removed by passage through an immunosorbent of rabbit antish sheep IgG (5 mL). The purity of the final product was examined by IEF, and amounts were

measured at each stage by enzyme-linked immunosorbent assay (ELISA). Separation of disulfide-bonded dimeric from monomeric λ chain was by passage through a column of Sephadex G-100 (Pharmacia) equilibrated with propionic acid (1 mol/L). The separated peaks were dialyzed into acetate buffer (4 mmol/L, pH 5.4) and stored at -20°C . To obtain normal λ chains, IgG λ was first prepared from normal human IgG by immunosorption. This IgG λ was then reduced and alkylated and the monomeric λ chains separated in propionic acid as above.

Monoclonal Anti-idiotypes

Anti- λ chain idiotypic (anti-Id [λ]). The isolated urinary λ chain was used to immunize a BALB/c mouse with a primary subcutaneous (SC) injection of 100 μg in Freund's complete adjuvant (CFA), followed by similar booster injections after 5, 7, and 9 weeks. The final injection was of 100 μg aqueous antigen intravenously (IV) three days before removal of the spleen for hybridization of the cells with the mouse myeloma NS-1 (P3-NS-1/1-Ag 4.1).¹¹ The procedures for growing colonies and cloning were as described,¹² selection being based on reactivity of supernatants in the ELISA system with idiotypic λ chain (λId), IgMId, and irrelevant light chains. To produce larger amounts, 10^7 hybridoma cells were injected intraperitoneally (IP) into Pristane-primed BALB/c mice, and antibody was purified from ascitic fluid by precipitation with ammonium sulfate followed by separation on a column of diethyl aminoethyl (DEAE)-trisacryl in phosphate buffer (5 mmol/L, pH 8) with a linear gradient to 50 mmol/L. The major peak was collected and its purity checked by electrophoresis.

Anticombined idiotypic (anti-Id [$\mu + \lambda$]). To obtain IgMId for immunization, a "rescue" hybridization was carried out by fusing tumor cells from the blood of patient LP with the mouse myeloma NS-O, a subline that synthesizes no mouse κ chain. Colonies producing IgM λ were cloned by limiting dilution and supernatants from confluent growth collected. The IgM was purified and prepared as an immune complex with mouse antihuman λ as described⁴ for immunization of mice. Selection of hybridomas was then based on reactivity with IgMId and not with normal IgM by ELISA and for the ability to bind to tumor cells in the presence of normal human serum.¹³

Binding ELISA to Assess Specificity

A preliminary assessment of specificity was carried out using λId or a pool of three λ Bence-Jones proteins coated directly onto a microtitre plate at 100 ng/mL. Monoclonal antibody was then added and bound mouse Ig detected with horseradish peroxidase (HRP)-labeled rabbit antimouse Ig (Nordic Labs, Maidenhead, England). Binding to IgM was investigated by the indirect procedure: rabbit antihuman μ chain (10 $\mu\text{g}/\text{mL}$) was coated onto the plate and IgM preparations, and either "rescue" hybridoma supernatants or macroglobulinemic sera were added, followed by MoAb as above.

Inhibition ELISA to Quantitate Relative Binding

This was established to measure the relative abilities of different λ -containing molecules to bind to the MoAb-Id(λ) and also to find the proportion of λId among normal λ chains. First λId was bound directly to the microtitre plate at 100 ng/mL, then a binding curve was constructed for anti-Id (λ) using HRP-rabbit antimouse Ig for detection. Having established the steepest part of the binding curve (40 ng/mL of antibody), this concentration of antibody was mixed with different dilutions of each inhibitor, and the resulting reduction in mouse antibody bound to the plate was measured. The concentration of inhibitor giving a 50% reduction in binding could then be compared for each molecular species, and the slope of the inhibition curves could indicate antigenic similarity. A major advantage of the

inhibition assay is that all inhibitors are compared in the fluid phase with no complications due to different coating efficiencies or to possible structural distortions occurring during binding to a solid phase.

Immunofluorescence

Testing of anti-idiotypes on the patient's dispersed tumor cells was by flow cytometry on the FACS III (Becton Dickinson, Mountain View, CA). For inhibition studies, normal human serum (50 μL) was added to culture supernatants (50 μL) or to purified antibody at $\sim 20 \mu\text{g}/\text{mL}$, before adding to the cells. Bound antibody was detected with fluorescent rabbit antimouse Ig.

Tissue Sections

Frozen tissue sections were used to assess reactivity of the anti-Id(λ) with normal tonsil and lymph nodes from nine patients with lymphoma. Cryostat sections (5 μm) were air-dried and stored at -70°C until required. Immediately before staining the sections were fixed in acetone for ten minutes and then stained by a two-layer immunoperoxidase technique,¹⁴ using HRP-rabbit antimouse Ig as the second layer and developing reaction product with diaminobenzidine tetrahydrochloride.

RESULTS

Production of λId by Tumor Cells

Neoplastic B cells from LP secreted in vitro free λ light chain (20 ng/h) and IgM (7.2 ng/h), values in the range of those found previously for patients with CLL.¹⁵ The levels of light chain (κ and λ) in a typical 24-hour urine sample from LP were 0.3 (κ) and 6.8 (λ) mg per 24 hours, which is below the detection level of most routine methods and requires sensitive IEF and immunofixation or other special techniques¹⁶ for identification. Identification of the monoclonal λ chain for LP by this technique has been reported.⁸ After purification of the urinary λId and passage through G-100 in 1 mol/L propionic acid, the disulfide-bonded dimer accounted for about 20% of total λ .

Monoclonal Anti-Id (λ)

In the first screen of selected hybridoma supernatants, seven clones were found to recognize λId and not pooled λ

Fig 1. Binding of MoAbs to target lymphoma cells from patient LP. Tumor cells were exposed to mouse MoAbs, and bound mouse IgG was detected with fluorescent rabbit antimouse Ig. (A) 1: Anti-human κ chain (10 $\mu\text{g}/\text{mL}$); 2: anti-human λ chain constant region (10 $\mu\text{g}/\text{mL}$); 3: antibody against heavy plus light chain idiotypic (anti-Id [$\mu + \lambda$] (10 $\mu\text{g}/\text{mL}$)). (B) 1: Anti-human κ chain (10 $\mu\text{g}/\text{mL}$); 2: anti-human λ chain constant region (10 $\mu\text{g}/\text{mL}$); 3: antibody against λ chain idiotypic (anti-Id [λ] (24 $\mu\text{g}/\text{mL}$); 4: anti-Id (λ) plus normal human serum (50%).

Fig 2. Comparison of binding of monomeric and dimeric λ chains to immobilized anti- λ constant region antibody. Rabbit antihuman λ chain constant region ($5 \mu\text{g/mL}$) was coated to the wells of a microtitre plate and exposed to various concentrations of idiotype λ chains from patient LP, previously separated into monomer and disulfide-bonded dimer. Detection of bound λ chain was by HRP-rabbit antihuman λ chain. ■—■, monomeric λ Id; ●—●, dimeric λ Id; ▼—▼, pool of three Bence-Jones proteins of λ type.

chains. Of these, three also recognized IgMId and not normal IgM, and the most vigorous of these was selected for expansion. Further tests of specificity showed the antibody to be unreactive with rescued IgM preparations (3 IgM λ) or 23 sera from macroglobulinemic patients (10 IgM κ and 13 IgM λ). The subclass of the antibody was IgG1.

Immunofluorescence showed good reactivity with tumor cells from LP, which was not affected by the presence of normal human serum (50%) (Fig 1). The antibody did not react with frozen sections of normal tonsil nor with nine lymph node specimens from patients with B cell lymphoma; antibodies to Ig constant region reacted normally with these sections.

Monoclonal Anti-Id ($\mu + \lambda$)

This antibody was selected by the usual criteria for anti-idiotypic considered for therapy, ie, it recognized IgMId

but not normal IgM by ELISA, and its binding to tumor cells from LP (Fig 1) was not inhibited by normal serum (50%). This antibody did not bind to λ Id by ELISA, and its binding to IgMId was unaffected by λ Id up to a concentration of $50 \mu\text{g/mL}$.

Nature of Determinant Recognized by Anti-Id(λ)

Monomeric and dimeric λ Id. It was of interest to determine the reactivity of the monoclonal anti-Id (λ) with monomeric or dimeric λ Id to see if the relevant determinant was more exposed on the monomer. Disulfide-bonded dimer and monomer were first assayed by ELISA using anti- λ constant region antibody on the plate and detecting bound λ with HRP-anti- λ . Results are shown in Fig 2 where it is clear that at saturation, monomer gives half the binding of dimer at equivalent concentrations. This is consistent with equal molar binding to the plate, with each bound dimer offering twice as many determinants as monomer to the detecting HRP-antibody. Apparently the monomer has not dimerized by noncovalent bonds under the conditions of the ELISA, presumably due to the routine presence of non-ionic detergent, Tween 20 (0.1%). A pool of three λ Bence-Jones proteins showed binding similar to that of λ Id dimer (Fig 2), suggesting that they are dimerized by disulfide bonds as has been found for most human λ chains.¹⁷

Comparison of the ability of the monomer and dimer to bind to the anti-Id (λ) was made by the inhibition ELISA (Fig 3). It was found that λ Id monomer was approximately $12\times$ more efficient than dimer on a weight basis ($6\times$ on a molar basis) in displacing the monoclonal anti-Id (λ) from binding, since the monomer caused 50% inhibition at 1.6 ng/mL , whereas 18.5 ng/mL of dimer was required (Table 1). There is also a deviation from parallelism for the dimer (Fig 3), suggesting that the antigenic determinant is not identical to that of the monomer.

Normal pooled λ chains. Reactivity of the anti-Id(λ) with normal λ chains was also quantitated by the inhibition ELISA (Fig 3). These λ chains were obtained from normal IgG λ by reduction and alkylation of the disulfide bonds followed by separation in 1 mol/L propionic acid and are therefore monomeric. It was found that $3.3 \times 10^4 \text{ ng/mL}$

Fig 3. Inhibition ELISA to compare the abilities of various λ -containing molecules to bind to monoclonal anti- λ chain idiotype. The assay depends on competing λ -containing molecules that bind in the fluid phase to the mouse anti-idiotypic antibody, thereby preventing its uptake by idiotype λ chain (λ Id) immobilized on the plate. The percentage reduction in bound mouse antibody was quantitated by HRP-rabbit antimouse Ig. ■—■, monomeric λ Id; ●—●, dimeric λ Id; ▼—▼, normal human monomeric λ chains; □—□, idiotype IgM λ .

Table 1. Measurement of the Ability of Various λ -Containing Molecules to React with Monoclonal Anti- λ Idiotype (Anti-Id (λ)) by an Inhibition Assay*

Inhibitor	Molecular Form	Concentration for 50% Inhibition (ng/mL)
Idiotypic λ (λ Id)	Monomer	1.6
	Dimer	18.5
Normal λ	Monomer	3.3×10^4
Idiotypic IgM† (IgMId)	Pentamer	2.5

*For this assay, λ Id was coated to the wells of a microtitre plate and mouse anti-Id (λ) at 40 ng/mL was added, either alone or mixed with different dilutions of each inhibitor. The resulting reduction in mouse antibody bound to the plate was measured and the concentration of inhibitor giving a 50% reduction in binding found.

†Concentration is in terms of the λ chain content.

was required for 50% inhibition (Table 1), ie, only one molecule in about 20,000 carries the same idiotypic determinant as the λ Id.

Tumor-derived IgMId. The rescued IgMId was found to be predominantly pentameric from its elution curve on AcA 22; its ability to displace the anti-Id(λ) from its binding to λ Id antigen is shown in Fig 3. The amount of IgMId is given in terms of the content of λ chain for direct comparison, and it can be seen (Table 1) that 2.5 ng/mL is required for 50% inhibition, a value close to monomer and much more efficient than dimeric λ Id.

It was also found that normal serum (1 in 10) failed to inhibit binding, whereas LP's serum inhibited binding by 50% at 1 in 640 dilution.

Additive binding to IgMId by anti-Id (λ) and anti-Id ($\mu + \lambda$). This was investigated by ELISA using limited antigen on the plate (25 ng/mL of IgMId coated indirectly) and finding a saturating concentration of anti-Id ($\mu + \lambda$) (2.7 μ g/mL). The anti-Id (λ) was then added to this in increasing amounts to see if additional binding could occur; the results are shown in Fig 4. Clearly the binding of anti-Id (λ) is independent of the presence of anti-Id ($\mu + \lambda$), since the binding curve is very close to the calculated additive curve. The graph also illustrates that the avidity of the anti-Id(λ) is considerably less than that of the highly avid anti-Id ($\mu + \lambda$), since the latter reached saturation of bound IgMId at 2.7 μ g/mL, whereas the former was still not saturating at 100 μ g/mL. However, the amount required for binding to cells (Fig 1) was 24 μ g/mL, well within a useable range. There was no significant binding of an irrelevant mouse MoAb at these concentrations.

DISCUSSION

A monoclonal anti-idiotypic antibody has been raised against tumor-derived λ light chain from a patient with CLL. The antibody is specific for idiotypic determinants on the λ chain but also recognizes λ chain in combination with μ chain either as soluble idiotypic IgM or on the surface of tumor cells. These properties are similar to those of polyclonal anti-idiotypes previously raised against tumor-derived light chains from four patients with CLL⁹ and demonstrate that this dual recognition is due to a single antibody. The study also confirms the generality of the approach and, since clones

Fig 4. Additive binding of two monoclonal anti-idiotypes to idiotypic IgM. The ability of anti- λ idiotype (anti-Id (λ)) to bind to target IgMId in the presence of a saturating amount of anti-heavy-plus-light chain idiotype (anti-Id ($\mu + \lambda$)) was assessed. Limited antigen (25 ng/mL of IgMId) was coated to the plate indirectly and then exposed to increasing concentrations of anti-Id (λ) in the presence of anti-Id ($\mu + \lambda$) at 2.7 μ g/mL. Total bound mouse antibody was detected by HRP-rabbit antimouse Ig. ▲---▲, anti-Id ($\mu + \lambda$) (2.7 μ g/mL) alone; ●---●, anti-Id (λ) alone; ■---■, anti-Id (λ) in the presence of anti-Id ($\mu + \lambda$); ▼---▼, calculated values for additive binding.

showing dual specificity were not rare, suggests the possibility of using such antibodies clinically.

However, there are two possible problems. First, more aggressive immunization is required for light chain as compared to IgM.⁹ This could perhaps be solved by coupling light chain to a carrier such as keyhole limpet haemocyanin. The second problem is that the antibody studied had a considerably lower avidity for idiotypic IgM than did the antibody against heavy plus light chain (combined) idiotype, the latter having a very high avidity. Since antibody avidities are variable, this need not be a general property, but more antibodies need to be studied.

Using this MoAb it has been possible to investigate further the nature of the antigen recognized. In the more common situation where antibodies are raised against combined idiotype, they rarely bind to free light chain, more often recognizing determinants dependent on a conformation involving heavy and light chains.¹⁰ This has also been found for anti-idiotypes raised against IgM idiotype in this laboratory, including the one described in this report. Thus the idiotypic determinants present on the isolated light chains that can induce antibodies that recognize IgM, and therefore must be displayed on the IgM molecule, are either pre-empted by other immunogenic structures or are not detected in the assay systems used. One exception to the failure of anti-idiotypic raised against IgM to recognize free light chain is seen for rheumatoid factors (RFs). The existence of a major cross-reacting idiotype (Wa) among human monoclonal IgM anti-IgG autoantibodies from unrelated individuals with cryoglobulinemia was first described using polyclonal antisera.¹⁸ More recently a MoAb generated against this IgM idiotype was shown to react with isolated κ chains from those IgM-RFs expressing the idiotype.¹⁹ The relevant deter-

minant was localized to the second complementarity-determining region of the κ chain and antibody raised against the isolated peptide bound to the IgM-RFs.

The use of the inhibition ELISA has allowed quantitation of the degree of binding of the antibody to various λ -containing molecules. The first point is that since it only recognized 1 in 20,000 molecules of normal λ , it can be considered to be idiotype specific. Second, binding by monomeric λ Id, which in antigen excess could be twice as efficient as dimer on a weight basis if the determinant is equally exposed on the two molecular species, is 12 times more efficient, indicating that masking or distortion of the determinant occurs during dimerization. However, the λ component of IgMId is almost as efficient as monomeric λ , suggesting that the determinant is exposed while λ Id is combined with μ chain and that, unlike the Mcg light chain studied by x-ray diffraction,²⁰ the dimer does not assume a similar

conformation to the μ - λ combination. The generality of this is unknown but raises the possibility that one of the reasons for the failure of polyclonal anti-IgM idiotypes to recognize free light chain could be due to the use of dimeric light chains in the test system.

Thus the earlier findings, reported in all four cases of CLL investigated⁹ and in an animal lymphoma,²¹ that polyclonal antibodies raised against idiotype light chains will recognize idiotype IgM have been confirmed using MoAb and should open the possibility of using such reagents for monitoring and perhaps treating B cell lymphoma.

ACKNOWLEDGMENT

We are grateful to H. McBride for raising the monoclonal anti-IgM indiotype, to Dr D.B. Jones for carrying out the tissue section staining, to A. Worth for help with the FACS analysis, and to M. Power for some protein preparations.

Studies Investigating Platelet Aggregation and Release Initiated by Sera From Patients With Thrombotic Thrombocytopenic Purpura

By John G. Kelton, Jane C. Moore, and William G. Murphy

Many patients with thrombotic thrombocytopenic purpura (TTP) have a platelet aggregating factor in their serum that may be pathologically linked with the disease process. To help characterize the type of platelet aggregation and platelet release induced by the sera from seven TTP patients, we measured the ability of a variety of inhibitors of platelet function as well as the ability of monoclonal antibodies (MoAbs) against platelet glycoproteins to inhibit TTP sera-induced platelet aggregation and release. These results were compared with the ability of the same inhibitors to block platelet aggregation induced by ristocetin, collagen, ADP, thrombin, and IgG-immune complexes. Monoclonal antibody directed against platelet glycoprotein Ib totally inhibited ristocetin-induced aggregation and release but had no effect on aggregation and release induced by the TTP sera or by any of the other platelet agonists. However, the MoAb against glycoproteins IIb/IIIa inhibited aggregation and release caused by TTP sera as well as by collagen, thrombin, and ADP but had no effect on

aggregation and release induced by ristocetin. The aggregating activity could be abolished by heparin but not by the serine protease inhibitor PMSF (1 mmol/L). And although monomeric human IgG and purified Fc fragments of IgG inhibited IgG-immune complex-induced aggregation and release, they had no effect on TTP sera-induced aggregation and release nor on aggregation and release induced by any of the other agonists. Consistent with these in vitro studies showing no effect of IgG were the in vivo observations that intravenous (IV) IgG was without effect when administered to three patients with TTP. This study indicates that although a von Willebrand factor (vWF)-rich preparation of cryoprecipitate enhances the in vitro platelet aggregation and release caused by sera from the seven TTP patients we studied, the pathway of aggregation and release is not via platelet glycoprotein Ib. Also the aggregating factor of TTP sera is not neutralized in vitro or in vivo by IgG.

THROMBOTIC thrombocytopenic purpura (TTP) is a life-threatening disease characterized by consumptive thrombocytopenia, schistocytic hemolytic anemia, fever, and acute arterial thrombotic complications especially within the cerebral circulation.¹ The thrombotic complications are due to the occlusion of small arteries by platelet thromboemboli. The pathogenesis of TTP remains uncertain, but the consumptive thrombocytopenia plus platelet thromboemboli suggest that in vivo platelet aggregation could participate in its pathogenesis. It is possible that the platelet aggregation could be mediated by a platelet aggregating factor with participation of von Willebrand factor (vWF).² A platelet aggregating factor in plasma or sera from patients with TTP has been described by two groups of investigators;^{2,3} however, the in vitro characteristics are not identical.²⁻⁴ There is also evidence that the vWF actively or passively participates in the pathogenesis of TTP. For example, Moake and colleagues described alterations in the vWF molecule in patients with TTP,^{5,6} observations confirmed by ourselves.² But again there is not total agreement about these observations.⁴

To study TTP sera-induced platelet aggregation in greater detail, we investigated whether monoclonal antibodies

(MoAbs) against platelet glycoprotein Ib and against glycoprotein IIb/IIIa could inhibit platelet aggregation and release initiated by TTP serum. Controls included platelet agonists that agglutinate platelets via platelet glycoprotein Ib (ristocetin) and other agonists (collagen and thrombin) that require glycoproteins IIb/IIIa for aggregation and release. The results of the study indicate that in vitro TTP sera-induced platelet aggregation and release occurs via glycoproteins IIb/IIIa and not Ib, and the platelet reaction is not affected by IgG.

MATERIALS AND METHODS

Patients and Controls

Sera from seven unselected patients with TTP were studied during the acute episodes before treatment. All patients had thrombocytopenia and schistocytic hemolytic anemia. In five of the patients, the pattern of vWF was analyzed by crossed immunoelectrophoresis before treatment was initiated. In all of these patients the large multimers of vWF were reduced or absent. Five of the patients had neurologic signs. One patient died, and postmortem examination confirmed the diagnosis as TTP.

Whole blood was collected into glass Vacutainer tubes (Becton Dickinson, Mississauga, Canada) containing no anticoagulant. The blood was allowed to clot spontaneously for a minimum of two hours and a maximum of 12 hours. The blood was centrifuged (2100 g for 20 minutes); the serum was transferred to plastic tubes and stored in aliquots at -70 °C. Before testing, the serum was thawed at 37 °C and then incubated for an additional 30 minutes at 37 °C to inactivate thrombin, and the pH was adjusted to 7.4.

Control sera were collected from healthy laboratory volunteers receiving no medications. This study was performed in accordance with the guidelines developed by the University-approved Ethics Review Committee.

Aggregating Agents

Platelet aggregation and release was induced using bovine achilles tendon collagen (final concentration, 55.1 µg/mL; Sigma Chemical Co, St. Louis), thrombin (final concentration, 2 U/mL; Fibrinex,

Ortho Diagnostics, Westwood, MA), adenosine diphosphate (ADP; final concentration, 10 $\mu\text{mol/L}$; Sigma), ristocetin (final concentration, 1.5 mg/mL; H. Lundbeck & Co, Copenhagen), and IgG immune complexes.

IgG immune complexes were prepared from human IgG. The human IgG was isolated from normal AB sera twice precipitated with 50% ammonium sulphate followed by a diethylaminoethyl (DEAE) Sephacel column (Pharmacia, Dorval, Quebec). The IgG was stored at -70°C at a final concentration of 10 mg/mL. IgG immune complexes were made by heating 0.5-mL aliquots (63 $^\circ\text{C}$ for 20 minutes). Before using, the largest complexes were removed by centrifugation at 10,000 g for five minutes. Purified Fc fragments were prepared from monomeric IgG using papain (100:1, wt/wt). Undigested IgG was separated from Fc by gel chromatography, and the completeness of separation was verified by analytic polyacrylamide gel electrophoresis (5% SDS-PAGE). The concentration of Fc was raised to 20 mg/mL by ultrafiltration and the sample frozen at -70°C before use.

Inhibitors of Platelet Aggregation/Release

The effects of aspirin (3.3 mmol/L), EDTA (1.6 mmol/L) and IgG (5 mg/mL) were tested for their ability to inhibit platelet aggregation and release.

Murine MoAbs 6D1 against human glycoprotein Ib, (IgG₁, final concentration 10.5 $\mu\text{g/mL}$) and 7E3 against IIb/IIIa (IgG₁, final concentration 15 $\mu\text{g/mL}$) were also used.⁷ These MoAbs were a gift from Dr B. Collier of the State University of New York at Stony Brook. A control MoAb lacking platelet glycoprotein activity was also tested at a final concentration of 15 $\mu\text{g/mL}$.

The effect of two protease inhibitors, heparin (0.5 U/mL), and phenylmethylsulfonylfluoride (PMSF) (1 mmol/L; Sigma) were tested for their ability to inhibit TTP-induced platelet release.

Performance of Platelet Aggregation and Release Studies

Preparation of test platelets. Twenty milliliters of whole blood was collected from different healthy donors into acid citrate dextrose, pH 4.5, (6:1, vol/vol). The platelet-rich plasma (PRP) was obtained by centrifugation (160 g for 20 minutes). The PRP was incubated with ^{14}C serotonin (Amersham, Oakville, Ontario) for 30 minutes at 37°C at a concentration of 0.5 μCi ^{14}C serotonin per mL PRP. Approximately 50% of the ^{14}C serotonin was taken up by the washed platelets giving a final specific activity of 1.84×10^{-4} μCi of ^{14}C serotonin per 10^6 platelets. The platelets were pelleted by centrifugation (1800 g for nine minutes) and resuspended in 10 mL of calcium and albumin-free Tyrode's solution, pH 6.2, containing 50 μL of apyrase. The apyrase (50 $\mu\text{g/mL}$) was prepared using standard techniques and inhibited aggregation induced by 10 $\mu\text{mol/L}$ ADP. The platelets were washed once by centrifugation (1200 g for seven minutes) and resuspended to a final count of 600,000/ μL in albumin-free Tyrode's solution, pH 7.4. Because the reactivity of the platelet preparations occasionally differed from donor to donor, platelets were collected from three ABO compatible donors, pooled and processed as described above.

In a second series of experiments the platelets were resuspended with human fibrinogen (Kabi, Sweden) at a final concentration of 2 mg/mL. In these studies the assay was performed at 37°C and the effects of inhibitors of aggregation and release investigated as described subsequently. In these experiments the cryoprecipitate preparation was not added.

Preparation of solution containing large multimers of vWF. Two units of cryoprecipitate prepared from healthy donors were pooled and diluted with 10 mL of 0.9% sodium chloride. The cryoprecipitate was defibrinated using 0.15 units anecrod (Arvin,

Connaught Labs Ltd, Willowdale, Ontario) per millimeter of dilute cryoprecipitate. The mixture was incubated for ten minutes at 37°C , centrifuged (2100 g for 20 minutes), and heat-inactivated for 30 minutes at 56°C . The solution was stored at -70°C before using. Immediately before using the solution was thawed at 37°C and then subjected to centrifugation (12,000 g $\times$ 10 minutes) to remove large aggregates. We have previously demonstrated that this preparation contains large multimers of vWF.²

Platelet release studies. Twenty microliters of test serum (pH 7.4) was mixed with 60 μL of ^{14}C -serotonin-labeled platelets. The platelet mixture was incubated at room temperature in microtitre wells containing a magnetic stir bar. Following a ten-minute incubation, 3 μL of the preparation containing the large multimers of vWF was added (final concentration of 0.05 units). The suspension was stirred for an additional ten minutes. Both incubations were done on a magnetic stir plate set at a slow speed. At the end of the final incubation period, 100 μL of 0.5% EDTA in saline was added to terminate the release reaction. The platelets were then observed for evidence of visible aggregates and scored as positive (aggregates) or negative (no aggregates). The microtitre plates were centrifuged for five minutes at 1500 g and 50 μL of the supernatant fluid was removed. This aliquot was added to 10 mL of scintillation fluid and the samples were counted in a liquid scintillation counter. The percent release was calculated as follows:

Percent Release =

$$\frac{\text{Release (test sample)} - \text{Background}}{\text{Total Platelet Radioactivity} - \text{Background}} \times 100$$

The background was defined as the supernatant fluid radioactivity from platelets handled identically to the test platelets except that buffer was substituted for serum. Total radioactivity was the radioactivity of the test platelet sample. A test result was defined as positive if there was greater than 20% release. All samples were tested in duplicate.

Inhibition of platelet release and aggregation. The experiments were performed as follows: 10 μL of the potential inhibitor (EDTA, aspirin, heparin, PMSF, IgG, Fc fragments, anti-GP Ib, anti-GP IIb/IIIa, or buffer) was added to 60 μL of the platelet suspension followed by a ten-minute incubation at 22°C . The TTP serum (20 μL) or agglutinating agent (20 μL of ADP, collagen, ristocetin, thrombin, or IgG immune complexes) was then added to the mixture, and it was stirred for ten minutes at 22°C . The fibrinogen-depleted cryoprecipitate was added and mixed for an additional ten minutes at 22°C . One hundred μL of 0.5% EDTA in saline was added to terminate the reaction. The microtitre plates were centrifuged, and the radioactivity of the supernatant was measured.

To investigate whether IgG prepared from normal pooled sera or control sera could inhibit TTP sera-induced platelet release, the following experiments were performed: The amount of platelet release initiated by four different TTP sera or one normal control serum was measured using the technique described previously. Control IgG at a final concentration of 1.2 mg/mL or control serum was incubated with each TTP serum for 20 minutes at 22°C . The ^{14}C -serotonin labeled platelets (60 μL) were added, and, after an additional 20-minute incubation at 22°C , the amount of release was measured. In these experiments the four TTP sera that were used were selected because their strong reactivity did not require the addition of the preparation rich in vWF to induce the release reaction.

The same experiment was repeated using the same TTP and control sera except that the IgG or control serum was preincubated with the platelets (22°C for 20 minutes) before addition of the TTP sera.

RESULTS

Case Report 1

A 45-year-old woman was admitted with diagnosis of TTP and was treated with plasma exchange, aspirin, and dipyridamole. After an initial partial response the illness relapsed. The patient was treated with 23 different plasma exchanges but did not respond. She also did not respond to 4 mg of vincristine. Intravenous (IV) IgG (Gamimune, Cutter Biologicals, Berkeley, CA) was administered over two days at a dose of 2 g/kg. There was no effect on either the platelet count or on the serum LDH level. The patient died two weeks later of intracerebral thrombosis complicated by hemorrhage. Postmortem examination confirmed the diagnosis of TTP.

Case Report 2

A 54-year-old woman was admitted with TTP. She had had an episode of TTP five years previously that had responded to plasma infusion and plasmapheresis and had been well for the subsequent five years. On this admission she was treated with both plasma infusion and plasmapheresis, and her platelet count was maintained above 150,000/ μ L by weekly 3-L plasma exchanges. Because of difficulties in maintaining vascular access, she was treated with IV IgG (IVEEGAM; Immuno, Vienna, Austria) at a dose of 2 g/kg. She did not respond, and her platelet count fell to 50,000/ μ L over the next week. She was again treated by a plasma exchange, and her platelet count promptly rose. She is currently maintained by weekly plasma exchanges.

Case Report 3

A 5-year-old girl with congenital chronic relapsing TTP has been treated over the past five years with intermittent (usually three per year) plasma infusions when her platelet count falls below 50,000 per μ L. This treatment results in a

prompt rise in platelet count and hemoglobin level that persists for weeks to months. She responds to plasma, stored plasma, and cryoprecipitate infusions. On one occasion she was treated with IV IgG at a dose of 3 g/kg (Sandoglobulin; Sandoz Laboratories, Dorval, Quebec) but did not respond to the treatment. Subsequent treatment with plasma infusions promptly raised the platelet count and hemoglobin level. Serum from this child was not used in the *in vitro* studies described in this report.

Results of the Platelet Aggregation and Release Studies

The results of the platelet aggregation and release studies are shown in Table 1. Collagen-induced aggregation and release were not affected by aspirin, heparin, or the MoAb against platelet glycoprotein Ib. It was totally inhibited by the MoAb against glycoproteins IIb/IIIa. ADP reacted similarly. Thrombin-induced aggregation and release were inhibited by heparin and by the MoAb against glycoprotein IIb/IIIa.

Ristocetin-induced aggregation and release were only inhibited by the MoAb against glycoprotein Ib. Purified Fc fragments were without effect. IgG-immune complex-induced aggregation and release were totally inhibited by monomeric IgG and purified Fc. TTP sera-induced aggregation and release were unaffected by aspirin and totally inhibited by heparin (high concentrations) and EDTA. It was not affected by the MoAb against glycoprotein Ib but was inhibited by the MoAb against IIb/IIIa. It was not affected by either monomeric IgG or purified Fc. An additional five IgG fractions were also tested for inhibitory capacity, including IgG obtained from a patient with two previous episodes of TTP and who was in remission. None of these IgG fractions had any effect on TTP sera-induced platelet aggregation and release.

The study investigating the inhibitory effect of control IgG or serum preincubated with the TTP sera showed that

The results of various inhibitors (shown along the top) on visible platelet aggregation (indicated by a + sign) and the percent ^{14} C serotonin release from platelets (noted within the brackets). The percent release was the mean of three or more experiments. The concentration of the aggregating agents and antagonists is given in the "Methods" section.

ND indicates not done.

neither control IgG nor serum affected the platelet release induced by the TTP sera. Similarly, preincubation of the test platelets with control IgG or serum did not block the effect of the TTP sera. The amount of platelet release initiated by the four different TTP sera with or without control IgG or serum ranged from 70% to 98%.

In the experiments in which fibrinogen was used at a physiologic concentration (2 mg/mL), the preparation rich in vWF was not used. Only three of the seven TTP serum samples caused release, and the amount of release was lower and ranged from 26% to 45% of maximum. However, the pattern of inhibition of release was identical to that noted in Table 1. In particular, the MoAb against platelet glycoprotein Ib was without effect, but the reaction was inhibited by the anti-IIb/IIIa antibody.

The TTP-induced platelet release could be entirely inhibited by heparin (0.5 U/mL). However, the aggregation was not caused by thrombin as shown by the lack of effect of PMSF. PMSF at a final concentration of 1 mmol/L had no effect upon the release reaction of seven different TTP sera. The release induced by these sera ranged from 64% to 100%.

DISCUSSION

The pathogenesis and optimal treatment of thrombotic thrombocytopenic purpura (TTP) remain uncertain. A number of hypotheses concerning the pathogenesis of TTP have been proposed: most are based on clinical observations, or on the results of *in vitro* studies, or on the response to certain therapeutic interventions. For example, untreated TTP has a mortality that may be as high as 90%.⁸ Treatment with antiplatelet agents reduces the risk of death, suggesting that *in vivo* platelet aggregation contributes to the morbidity and mortality of TTP.⁹ Supporting this hypothesis are postmortem reports of patients with TTP who have disseminated platelet thromboemboli in their small vessels.⁸ Also consistent are reports of platelet aggregating factors in the plasma of some patients with TTP.^{2,3} It is possible that by characterizing and identifying the aggregating factor, a more effective therapeutic strategy for dealing with this disorder might be developed.

In vitro and *in vivo* studies also support an active or passive role for vWF in the pathogenesis of the disorder. Moake and associates demonstrated abnormal patterns of vWF in patients with chronic relapsing TTP, an observation confirmed by ourselves.² Consistent with the hypothesis that vWF participates in the disease process are two other observations. First, we have shown that the *in vitro* reactivity of a platelet aggregating factor in the serum of some patients with TTP can be enhanced by the addition of a preparation rich in large multimers of vWF.² And second, pathologic studies have demonstrated the presence of vWF in occluded arteries from patients with TTP.¹⁰ Because vWF-induced platelet agglutination involves the platelet glycoprotein Ib, one might hypothesize that blocking this interaction might inhibit TTP sera-induced platelet aggregation and release. To investigate this issue more directly, we studied the effect of a variety of inhibitors of platelet aggregation on the aggregation and release induced by TTP sera. The results of

these aggregation and release studies were compared with results obtained using other platelet agonists. We found that the *in vitro* platelet aggregation and release initiated by TTP sera is mediated via platelet glycoproteins IIb/IIIa; and, as another group of investigators recently reported, glycoprotein Ib is not involved.⁴ Hence our results argue strongly against the reaction being identical to ristocetin-induced agglutination. The MoAb against glycoprotein Ib totally inhibited ristocetin-induced agglutination and release but had no effect on TTP, collagen, ADP, or thrombin-induced aggregation and release. In contrast, the MoAb against glycoprotein IIb/IIIa had no effect upon ristocetin-induced agglutination and release but inhibited the TTP sera-induced aggregation and release as well as the aggregation and release caused by the other agonists. Certain characteristics of TTP sera-induced platelet aggregation are similar to thrombin-induced platelet aggregation. In particular, it can be inhibited by heparin (Table 1). The observation raises the question of whether the TTP aggregating factor could be an artifact, such as thrombin, generated during blood collection. Two observations argue strongly against this possibility. First, as we previously demonstrated,² the thrombin-specific inhibitor DAPA was without effect. Second, PMSF, a serine protease inhibitor, also was without effect.

The observation that TTP sera-induced platelet release occurs through glycoprotein IIb/IIIa and not Ib should not be interpreted as indicating that vWF is not involved in the disease pathogenesis. It has been shown that vWF can also interact with glycoprotein IIb/IIIa, and modifications of the molecule dramatically increase its reactivity.^{11,12} Yet the mechanism of aggregation or characteristics of the inhibitory effect of normal plasma that result in remission in TTP remain uncertain. A role for IgG in either initiating the illness or controlling it has been proposed by one group.⁴ Elevated levels of platelet-associated IgG have been described in patients with TTP by several groups of workers, including ourselves; others have described circulating immune complexes in these patients. Together these observations might indicate that IgG immune complexes mediate the platelet aggregation. Indeed, IgG immune complexes are potent inducers of platelet aggregation, and aggregation induced by these complexes can be inhibited by IgG or the Fc portion of the molecule. However, our current *in vitro* and *in vivo* studies suggest that it is unlikely that IgG plays a causal or protective role in TTP. *In vitro* platelet aggregation initiated by IgG aggregates did not react similarly to the TTP sera-induced platelet aggregation in that the former could be blocked by either the addition of monomeric IgG or Fc. In contrast, both intact IgG and purified Fc were without effect upon TTP-induced platelet aggregation and release. These results are different from those obtained by another group of investigators studying TTP sera-induced platelet aggregation. They reported that IgG either from a control population or from a patient following recovery from TTP could neutralize the platelet aggregating factor.¹³ The reason for the difference in results between groups is uncertain and could be due to differences in experimental techniques. However, our *in vitro* data, failing to document a role for IgG in neutralizing TTP sera-induced platelet aggregation, is

further supported by the observation that high doses of IV IgG did not produce a remission in three patients with TTP. Although other investigators have reported an apparent response of TTP patients to IV IgG,¹⁴ such observations should be interpreted with caution. It is possible that the remission of the disease was spontaneous and only coincidentally linked to the IV IgG. It should be noted that two of the patients described in this report who failed therapy with IV IgG subsequently responded to more conventional therapy.

In summary, our studies demonstrate that TTP sera-

induced platelet aggregation and release is mediated via platelet glycoproteins IIb/IIIa. Although a preparation rich in vWF enhances the reaction in vitro, the pathway of release is not through glycoprotein Ib.

Prognosis of Chronic Lymphocytic Leukemia: A Multivariate Regression Analysis of 325 Untreated Patients

By Jung S. Lee, Dennis O. Dixon, Hagop M. Kantarjian, Michael J. Keating, and Moshe Talpaz

Three hundred twenty-five previously untreated patients with chronic lymphocytic leukemia were analyzed to identify significant prognostic factors for survival. Univariate analysis identified the following characteristics associated with survival: (1) clinical characteristics: age, race, sex, performance status, lymphadenopathy, and hepatosplenomegaly; (2) hematologic parameters: WBC count, absolute lymphocyte and granulocyte counts, hemoglobin level, and platelet count; and (3) biochemical parameters: serum albumin, calcium, uric acid, lactate dehydrogenase, alkaline phosphatase, BUN, and creatinine. Multivariate regression analysis in a randomly selected training subset of 217 patients demonstrated that the combination of uric acid, alkaline phosphatase, lactate dehydrogenase, external lymphadenopathy, and age had the strongest predictive

relation to survival time. The resulting model was validated in the remaining independent subset of 108 patients and led to classification of patients into low, intermediate, and high-risk groups with five-year survival rates of 75%, 59%, and 14%, respectively, and with distinctively different annual mortality rates ($P < .01$). Both the regression model and Rai staging were highly effective in identifying risk groups among the entire patient population ($P < 0.001$). Overall the regression model was superior to Rai staging in defining prognostic risk groups. In addition, it was able to separate patients into significantly different risk categories within each Rai stage, thus improving on the prognostic prediction of individual patients with chronic lymphocytic leukemia.

© 1987 by Grune & Stratton, Inc.

THE HIGHLY VARIABLE clinical course of chronic lymphocytic leukemia (CLL) poses difficulties in the evaluation of prognosis and the efficacy of therapy in individual patients as well as in clinical trials. Since the concept of clinical staging of CLL was introduced by Dameshek,¹ Rai et al² proposed a clinical staging system based on routine clinical and hematologic features that has subsequently been confirmed.^{3,4} Other studies have reported the importance of the absolute lymphocyte count, splenomegaly, hemoglobin levels, and the extent of lymphoid organ involvement in an attempt to improve this classification.⁵⁻¹¹ A new staging system, recommended by the International Workshop of CLL (IWCLL),¹² limits the clinical stages of CLL to three. All staging systems identify a high-risk group of patients defined by the presence of anemia or thrombocytopenia.⁵⁻¹⁴ In the remaining patients, who represent 70% to 80% of all cases, there is considerable variability in the course of the disease that is not well explained by the staging system. More recent studies have attempted to demonstrate the prognostic significance of immunologic parameters, bone marrow histopathologic pattern, and cytogenetics,¹⁵⁻²⁵ but the relative importance of each of these factors has not been determined.

The development of a prognostic model provides an objective estimate of an individual patient's prognosis, allowing group imbalance adjustments in comparing treatments and providing a basis for risk-directed therapy. Given the importance of adapting therapy to the severity of a disease that has a variable clinical course, we sought to identify significant prognostic factors and to develop a regression model aimed at stratifying patients according to prognosis for survival.

MATERIALS AND METHODS

Diagnostic Criteria

The diagnosis of CLL was based on the history, physical examination, peripheral blood smears, and bone marrow examination, with more than 15×10^3 lymphocytes/ μ L in the peripheral blood and at least 40% bone marrow lymphocyte infiltration.²⁶ Patients with poorly differentiated lymphocytic lymphoma, leukemic forms of well-differentiated diffuse lymphocytic lymphoma without initial bone marrow or peripheral blood involvement, prolymphocytic leu-

kemia, and lymphosarcoma cell leukemia were excluded from the study.

Patient Population

A total of 525 patients was registered at M. D. Anderson Hospital with the diagnosis of CLL between 1970 and 1983. Forty-seven patients had an incomplete evaluation mainly because of referral for other types of malignancy. Fourteen additional patients did not meet the diagnostic criteria on their initial evaluation, and follow-up information failed to confirm the diagnosis. One hundred thirty-nine patients had received treatment prior to admission. Thus 325 previously untreated patients were included in the analysis.

Among the 325 patients, 28% have never received any treatment after referral, 45% received single agent or combinations of conventional oral chemotherapy (chlorambucil, prednisone, and cyclophosphamide), and 27% received combination chemotherapies (adriamycin, cytosine arabinoside, cyclophosphamide, vincristine, and prednisone).

Prognostic Factor Analysis

Forty-one clinical and laboratory characteristics documented at initial evaluation were examined in the prognostic factor analysis. These were age, sex, race, year of diagnosis, interval between diagnosis and referral, performance status, symptoms (fever, weight loss), previous episodes of infection, hemolytic anemia or autoimmune thrombocytopenia, spleen and liver size (in cm below the costal margin), extent and site of lymphadenopathy (external, mediastinal, and retroperitoneal), hemoglobin (Hb) concentration,

peripheral WBC and platelet counts, differential counts of WBC in peripheral blood, 12 channel-automated serum biochemical parameters, serum immunoglobulin levels, and bone marrow parameters including cellularity and differential count. In addition, the presenting Rai classification stage was considered.

Statistical Methods

Survival curves were plotted according to the method of Kaplan and Meier.²⁷ Comparison of curves was based on log-rank tests.²⁸ Prognostic-factor analyses are sometimes criticized because of failure to identify an independent population in which the regression model can be validated.²⁹ For this purpose we randomly divided the 325 cases into training and test subsets containing 217 and 108 cases, respectively, so that we could identify important prognostic factors in one set of data and validate them in a second.²⁹

Using patient characteristics identified in univariate analyses, a proportional hazards regression analysis³⁰ was carried out in the training set cases. We assumed that the hazard rate (the instantaneous risk of death among patients having survived until time t) has the form

$$\log \frac{\lambda_i(t)}{\lambda_0(t)} = \beta_1 z_{1i} + \beta_2 z_{2i} + \dots + \beta_p z_{pi},$$

in which $\lambda_i(t)$ is the hazard rate for the i th patient whose coded patient characteristics are $z_{1i}, z_{2i}, \dots, z_{pi}$. $\lambda_0(t)$ is the hazard rate for a patient for whom all characteristics are coded 0.

Measured characteristics were coded by initially dividing the cases into a maximum of five subgroups of about equal size and then pooling subgroups with similar survival curves.

To identify the characteristics to be included, we used the forward stepwise selection approximation suggested by Peduzzi et al.³¹ Characteristics entered the model according to their level of significance, after adjusting for the influence of the ones already selected, until the p -value for adding another characteristic exceeded 0.05. The data were then re-analyzed, with only the characteristics identified, using the more accurate maximum partial likelihood ratio statistics in the forward stepwise selection and stopping when the p value for adding an additional variable was above 0.01.

To assess the quality of the model, we: (1) divided the training set cases into three risk groups according to the fitted hazard rates and compared the corresponding survival curves; (2) repeated the procedure for test set cases; and (3) re-estimated the regression coefficients for the characteristics in the model based on cases in the test set. A characteristic was excluded from the model, and the whole process was restarted if the new estimate failed to exceed its standard error.

Smoothed estimates of annual mortality rates were derived as suggested by Simes and Zelen.³² The BMDP library of programs³³ was used for all analyses. The BMDP special function RNDU was used for the random assignment of cases to the training and test subsets.

RESULTS

The overall median survival from the date of referral to our institution was 5.4 years; 25% of patients survived beyond 10 years, while 10% of patients died within 1 year. At the time of analysis, 192 of 325 patients had died, and median follow-up among the 133 surviving patients was 5.2 years. Among the 150 patients with known causes of death, this was due to complication of advanced CLL in 33%; infections, predominantly pneumonia, in 25%; unrelated diseases (cardiovascular, renal) in 23%; second malignancy in 7%; other leukemias in 6%; and bleeding in 5%. Patient

characteristics of the training and test sets were comparable, and survival curves were almost identical (Fig 1).

Univariate Analysis of Prognostic Factors

Clinical characteristics. The univariate analysis of the clinical characteristics is presented in Table 1. The median age was 62 years (range 25 to 88 years), and survival progressively declined with advancing age. Males, representing 61% of our patients, and blacks, representing 9%, had significantly shorter survival than other patients. The number of patients referred to our institution was fairly even throughout the period, and there was no difference in survival by year of diagnosis, despite differences in therapy and supportive care throughout these periods of time. Fifty-six percent of patients were referred within 1 month of diagnosis and had significantly shorter median survival than others. Early referrals (within 1 month of diagnosis) tended to have advanced disease (Rai 3 or 4) more frequently than later referrals (32% v 13%). Poor performance status, symptomatic state, and weight loss were all associated with shorter survival. Patients who presented with external lymphadenopathy at any site greater than 1 cm, mediastinal lymphadenopathy, or hepatosplenomegaly had a significant survival disadvantage, although the degree of hepatosplenomegaly did not influence survival.

Hematologic characteristics. Hemoglobin concentration, platelet counts, WBC counts, absolute lymphocyte counts, and percentage of polymorphonuclear cells in the peripheral blood influenced survival. A distinct stepwise relationship was noted between the hemoglobin levels and survival but not between platelet count and survival. The absolute WBC counts and absolute lymphocyte counts in the peripheral blood were inversely associated with survival, whereas the percentage of polymorphonuclear cells was directly related to improved survival.

Serum biochemical parameters and immunoglobulins. All the biochemical parameters, except serum bilirubin levels, demonstrated a strong correlation with survival. Survival of 17 patients with monoclonal gammopathy was not significantly different from the survival of the remaining patients. The immunoglobulin levels, available for 210 patients without monoclonal gammopathy, failed to demonstrate any association with survival.

Bone marrow studies. Bone marrow differential counts were available in 185 patients and cellularity in 207. Bone

marrow cellularity and percentage of lymphoid cells in the bone marrow differential were inversely associated with survival, while higher percentages of myeloid (>5%) and erythroid (>10%) cells had a significant positive influence on survival.

Rai stage. Survival by Rai stage is shown in Fig 2. Rai 0 patients have not reached a median survival. Median survivals of Rai 1 and 2 patients were 6 years and 4.2 years, respectively. There was no difference in median survival between Rai 3 and 4 patients.

Multivariate Regression Analysis

Forward stepwise selection-regression analysis, using the cases in the training set, resulted in selection of serum uric acid level, performance status, presence of external lymphadenopathy, serum creatinine level, and age, in the order listed, all with *P* values less than 0.01. This model, although confirmed in the test set of cases, depended on performance status, which is a subjective measurement, in a retrospective analysis of chart review.

A regression analysis, excluding performance status, selected the following: uric acid level, alkaline phosphatase

level, lactate dehydrogenase level, presence of external lymphadenopathy, and age, all with levels less than .01 (Table 2). Risk scores were calculated for each patient by using the regression equation (Table 2). Patient risk score distribution is shown in Fig 3. The training set was divided into three risk groups, using cut-points of 1.7 and 3.0. Survival curves for these low, intermediate, and high-risk groups are given in Fig 4. The regression model was validated

Table 2. Multivariate Analysis of Prognostic Factors in CLL

Characteristic	Code	Training Set	Testing Set	Total Population
I. Summary of Regression Model Analysis Relating Survival to Admission Features*				
Uric acid (mg/100 mL)	0 = ≤ 4 ; 1 = 4.1-6; 2 = 6.1-8; 3 = > 8	0.46 (0.12)	0.47 (0.16)	0.44 (0.10)
Alkaline phosphatase (mU/mL)	0 = ≤ 80 ; 1 = > 80	0.51 (0.19)	0.43 (0.27)	0.50 (0.15)
LDH (mU/mL)	0 = ≤ 225 ; 1 = 226-350; 2 = > 350	0.46 (0.13)	0.29 (0.19)	0.42 (0.11)
External lymphadenopathy	0 = no; 1 = yes	0.88 (0.25)	0.63 (0.33)	0.83 (0.20)
Age (in years)	0 = ≤ 50 ; 1 = 51-60; 2 = 61-70; 3 = > 70	0.28 (0.10)	0.53 (0.16)	0.35 (0.09)
II. Regression Model				
$\ln \frac{\lambda_i(t)}{\lambda_o(t)} = 0.44 \text{ (uric acid)} + 0.50 \text{ (alkaline phosphatase)} + 0.42 \text{ (LDH)} + 0.83 \text{ (external lymphadenopathy)} + 0.35 \text{ (Age)}$				

*Entries are regression coefficient and standard errors.

by demonstrating significant segregation of risk groups in the test set of patients ($P < 0.001$) (Fig 5).

Re-estimation of the regression coefficients for the five characteristics, using only the cases in the test set, shows comparable estimates to those of the training set, further confirming the importance of these variables in an independent population and validating the model (Table 2). The final estimates used in the regression equation are derived from the 307 patients with complete data from the combined training and test subsets (Table 2).

The prognostic significance of several patient characteristics available only on smaller subsets of patients (generally the more recent ones) was analyzed. Bone marrow biopsy findings were available on 185 patients. When various regression models were fit that included terms for uric acid level, external lymphadenopathy, alkaline phosphatase level, LDH level, age, and one or more of the bone marrow biopsy findings, only the percentage of myeloid cells made a significant but marginal contribution ($P = 0.035$).

Assignment of patients to risk groups using the detailed regression equation is inconvenient for routine clinical use. We examined several simplified alternative models in which all of the characteristics were limited to two categories. One of these, with uric acid coded 0 if ≤ 7.0 and 1 if > 7.0 , with LDH coded 0 if ≤ 325 and 1 if > 325 , and with age coded 0 if

≤ 60 and 1 if > 60 , produced a separation of survival curves into three groups that was nearly as good as for the detailed model. The new equation is: $\ln [\lambda_i(t)]/[\lambda_o(t)] = .68 \text{ (uric acid)} + 0.52 \text{ (alkaline phosphatase)} + 1.13 \text{ (LDH)} + 0.82 \text{ (external lymphadenopathy)} + 0.59 \text{ (age)}$.

Choosing cutpoints of 1.0 and 2.2 leads to risk groups having survival curves shown in Fig 6. The low-risk (score ≤ 1.0) group includes only patients with LDH ≤ 325 and no more than one unfavorable characteristic among uric acid, alkaline phosphatase, external lymphadenopathy, and age. The intermediate-risk (score 1.1 to 2.2) group includes patients with LDH > 325 and at most one unfavorable characteristic, or LDH ≤ 325 and two to three other unfavorable characteristics. The high-risk (score > 2.2) patients are those with LDH > 325 and two other unfavorable characteristics or those with any four or more unfavorable characteristics. Table 3 summarizes these criteria for easier clinical application.

Comparison of the Regression Model with Rai Staging

The distribution of patients by different risk groups and Rai stages is shown in Table 4. We evaluated the capacity of the regression model to identify groups of patients with different survivals within each of the Rai stages. As shown in Table 5, the regression model was useful in identifying patients at high risk even in the Rai 0, 1, and 2 categories. It

also identified patients with relatively better prognosis among Rai 1 to 2 or 3 to 4 stages, compared to their expected median survival by Rai stage.

Changes in Pattern of Referral and Influence of Therapy on Survival

The difficulties in evaluating the effect of therapy in patients referred over a period of 13 years and who have received multiple therapies sequentially for a chronic disease are obvious. Recently, patients with advanced Rai 3 and 4 disease have been treated with intensive combination chemotherapy such as prednisone, vincristine, cytosine arabinoside, cyclophosphamide, and adriamycin (POACH). The patterns of supportive care have also been relatively similar.

To suppose the possible effect of change of therapy, patients were divided into two equal groups, before 1976 and since 1976, which also corresponded to the time when more intensive regimens were being introduced for late-stage CLL. As shown, no change in the referral pattern by Rai staging was observed. Overall the median survival was similar in the two periods. More importantly, within early

*Unfavorable characteristics: Uric acid > 7.0 mg/100 mL; alkaline phosphatase > 80 mU/mL; external lymphadenopathy present; and age > 60 years.

Table 4. Distribution of Patients by Risk Category and Rai Stages (307 Patients)

Rai Stage	No. of Patients (percent)		
	Risk Category		
	Low	Intermediate	High
0	41 (13)	16 (5)	—
1-2	35 (11)	125 (41)	18 (6)
3-4	11 (4)	34 (11)	27 (9)

and late Rai stages, by year of therapy (Table 6), no obvious change in median survival was observed either, indicating the stability of the population course despite the variability of therapeutic approaches over this period of time.

DISCUSSION

The identification of the prognostic factors that contribute to the heterogeneity of CLL disease is useful for individual prognostication and for therapeutic planning. This analysis of 325 previously untreated CLL patients from a single institution identified 29 characteristics strongly associated with survival duration. The study confirms the prognostic importance of several previously described features. The adverse prognosis of characteristics such as weight loss, performance status, hepatomegaly, splenomegaly, increased WBC and lymphocyte counts, elevated serum alkaline phosphatase, LDH, and uric acid levels probably reflect increased tumor burden. The poor prognosis associated with anemia and thrombocytopenia probably measures bone marrow function compromise secondary to the increased leukemic infiltrate.¹⁻¹⁴ Abnormal biochemical parameters such as the serum calcium, albumin, and BUN and creatinine levels had significant adverse influences on survival, possibly indicating a poor host biological status and organ dysfunction.

Monoclonal gammopathy, mostly involving IgM, was present in 7% of patients.³⁴⁻³⁶ The presence of monoclonal gammopathy and the level of serum immunoglobulins were not associated with survival differences.²⁴ Bone marrow disease features correlated with peripheral blood patterns. The extent of marrow involvement expressed by the cellularity and the percentage of lymphoid cells were inversely correlated with survival.^{37,38} While the importance of histo-

Rai 3-4	29	37	0.65

pathologic patterns of bone marrow involvement, B cell markers, and cytogenetics have been appreciated recently,¹⁵⁻²⁵ these features were excluded from our analysis because they were available in only a small fraction of the patients.

Confirmation of the validity of a regression model in an independent population is essential for further clinical application.²⁹ In this study the regression model was derived from a training set of two thirds of patients and confirmed in the test set of the remaining one third. The derived regression model segregated patients into three separate low-, intermediate-, and high-risk groups with 5-year survival rates of 75%, 59%, and 14% respectively. Four of the five characteristics included in the model (uric acid, alkaline phosphatase, LDH, external lymphadenopathy) are probably indicators of high tumor burden, cellular turnover, or aggressive disease. The fifth characteristic (age) is host-related and may reflect the influence of a combination of different measurements of host status, such as organ dysfunction, tolerance to therapy, and other medical illnesses. It is interesting that the annual mortality rate in each risk group remains significantly different throughout the follow-up period. Annual death rates ranged from 2% to 9% for the low-risk, 9% to 23% for the intermediate-risk, and 31% to 42% for the high-risk groups (Fig 7). This supports the concept that CLL heterogeneity is not simply due to detection of patients at different time intervals from onset of disease but that it is truly due to different disease biology. CLL may thus represent a spectrum of diseases with significantly disparate biologic patterns and therapeutic implications. Future studies of cellular markers, cytogenetics, oncogenes, and growth patterns in CLL may help identify these CLL subcategories as different entities that can presently be categorized prognostically on the basis of clinical and biochemical parameters.

The Rai classification is presently widely accepted and confirmed as a useful clinical staging in CLL.² Any proposed new classification, or prognostic model, should provide added value to the Rai staging. Our regression model was superior to the Rai staging in predicting prognosis in the overall

**Fig 7. Risk of death per year for patients in different risk groups.**

population and in the test set. More importantly, it was able to identify, within the various Rai stages, groups of patients whose prognosis was different from that predicted by the Rai classification. For example, 28% of patients with Rai stage 0 could be predicted by the risk model to have a much inferior prognosis and a median survival of only 3.5 years. On the other hand, 20% of patients with Rai 1 or 2 did twice better, and 10% did twice worse than their predicted Rai staging prognosis. It appears, therefore, that the new prognostic model, which incorporates several parameters reflecting tumor burden, disease aggressiveness, and host factors, refines further the resolution of individual prognosis. Thus the use of the regression model alone or combined with the Rai staging should improve our understanding of CLL disease, allow better prediction of individual prognosis, and direct the need and timing of different therapies.

The shortcomings of analysis of prognostic factors in patients with chronic illnesses who receive multiple treatments sequentially are obvious. Changes in the patterns of referral and in therapeutic strategies may also affect the natural course of the disease and modify the relative importance of different prognostic factors.³⁹⁻⁴² In this study there was no change in the referral pattern or in overall survival in time for the total CLL population (Tables 1 and 6). More importantly, there were no significant survival differences even within early and late Rai stages, despite the changes in therapy in the latter category (Table 6). This indicates the stability of the course of CLL disease in time, supporting the validity of the prognostic factors derived.

In summary, our analysis of prognostic factors in CLL identified important clinical and biochemical variables that affected survival and resulted in a regression model dividing patients into three different risk groups. The improved ability to estimate the individual prognosis of patients with CLL should assist in the design and analysis of subsequent clinical trials.

Functional Differentiation of Normal Human Neutrophils

By Lewis Glasser and Roger L. Fiedlerlein

In the past differentiation of human neutrophils has been defined by morphology, cytochemistry, or surface markers. In our experiments we have sequenced the various events that occur during the functional differentiation of the normal human neutrophil and have also examined some of the functional properties in relationship to surface markers and biochemical events. Granulocytes were obtained from the bone marrow and blood of hematologically normal individuals. Cells were separated into different stages of maturation by their physical properties using counterflow centrifugal elutriation and density gradient separation. Three cell fractions were obtained that were enriched for either immature myeloid cells, band neutrophils, or segmented neutrophils. Since the enriched fractions were not entirely pure, methodologies for functional assays were chosen that allowed cytologic evaluation of the functional

capacity of each cell type. The criteria used to classify the stages of differentiation included both morphology by light microscopy and DNA labeling with tritiated thymidine. Various neutrophilic properties were studied: Fc receptors, complement receptors (CR₁, CR₃), phagocytosis of both live and dead opsonized *Staphylococcus aureus*, microbial killing of *S aureus*, NBT dye reduction after cellular stimulation with endotoxin, and chemotaxis. Our results indicate that the functional properties of the neutrophil appear in a distinct order. The sequence for the functional differentiation of the human neutrophil appears to be the following: Fc receptors → immune phagocytosis → complement receptors → oxygen-independent microbial killing → oxygen-dependent microbial killing → chemotaxis.

© 1987 by Grune & Stratton, Inc.

DIFFERENTIATION of human neutrophils is traditionally defined by the morphology of stained cells as seen by light microscopy. Schilling divided developing neutrophils into six morphologic subtypes: myeloblasts, promyelocytes, myelocytes, metamyelocytes, band neutrophils, and segmented neutrophils.¹ Subsequent ultrastructural cytochemical studies showed the sequential acquisition of primary and secondary granules, providing additional criteria for accurately assessing the stages of neutrophilic development.² Although such a classification tends to create an impression of step-like transitions rather than a continuous process, it provides useful and easily understood reference points for keying developmental events in the life history of the neutrophil.

With the development of immunologic techniques and monoclonal antibodies (MoAbs), the sequential appearance of surface markers on the developing neutrophil is now being catalogued.³⁻⁷ In addition to morphologic, enzymatic, and antigenic changes, functional changes also occur during differentiation. The neutrophil becomes more deformable, more adherent to surfaces, more actively forms pseudopods, more avidly ingests particles, and becomes more actively motile.⁸ The maturation sequence of the functional properties of the neutrophil has not yet been determined. Previous studies in our laboratory on leukemic cells suggested that the various functional properties of the neutrophil appear in a distinct order during cell development.⁹ In the present study we have sequenced the various events that occur during the functional differentiation of the normal human neutrophil. Granulocytes were isolated from the bone marrow and blood and separated into different stages of maturation by their physical properties using counterflow centrifugal elutriation and density gradient centrifugation. Three leukocyte fractions were obtained. These were enriched or purified for either segmented neutrophils, band neutrophils, or immature myeloid cells. The enriched fractions were not entirely pure. Thus methodologies were chosen that allowed cytologic evaluation of each stage of differentiation. Phagocytosis, bacterial killing, chemotaxis, nitroblue tetrazolium dye reduction, and opsonic receptors were evaluated. Our results indicate that phagocytosis is acquired early, followed by

nonoxidative microbial killing, and that oxygen-dependent microbial killing and chemotaxis represent the terminal stages of functional differentiation.

MATERIALS AND METHODS

Bone marrow samples. Specimens were obtained from seven paid hematologically normal volunteers of the hospital staff, two hematologically normal individuals undergoing heart surgery, and one patient with Hodgkin's disease. Informed consent was obtained. Not all tests were performed on all specimens. Marrow was aspirated from the iliac crest or sternum. Particles were disrupted by successively passing the sample through 22-G and 25-G needles. Cells were resuspended in 6% hydroxyethyl starch in 0.9% sodium chloride (American McGaw, Irvine CA), allowed to settle at room temperature, and the leukocyte-rich supernatant collected. Segmented neutrophils and eosinophils were removed by Ficoll-Hypaque separation (sp. gr. 1.077) and residual erythroid cells by hypotonic lysis.¹⁰ Nucleated bone marrow cells were then resuspended in elutriation medium consisting of RPMI 1640 and 5% fetal calf serum.

Counterflow centrifugal elutriation. Bone marrow cells were fractionated by centrifugal elutriation using a Beckman J2-21 centrifuge, Je-6B rotor, standard chamber, and Cole-Parmer Masterflex peristaltic pump.¹¹ All procedures were done at 22 °C. The rotor speed was 1740 ± 10 rpm. Fifty-milliliter samples were collected at each flow rate for a total of 16 fractions. Fractions that were similar were combined when necessary to increase the yield. The fractions were further enriched, if necessary, eliminating segmented neutrophils using Ficoll-Hypaque separation. The viability of the cells was determined in each fraction prior to testing using eosin-Y dye exclusion.¹²

Segmented neutrophils were prepared by collecting venous blood in heparin, adding 2 mL of a 6% hydroxyethyl starch solution to 7

mL of whole blood, harvesting the leukocyte-rich plasma, and eliminating the RBCs by hypotonic lysis. The blood leukocytes were resuspended in elutriation medium and then fractionated using centrifugal elutriation. Monocytes were effectively removed by the elutriation procedure. Conditions were similar to the separation procedure for bone marrow.

Criteria used to classify stages of neutrophil differentiation. Stages of neutrophil differentiation were evaluated by morphologic criteria from smears stained with Romanowsky dyes and by autoradiography after DNA labeling with tritiated thymidine.¹³ Nuclei were considered labeled if five or more grains were counted. The criteria are listed below:

(1) Myeloblasts range from 15 to 20 μm in diameter and have round nuclei with stippled chromatin with one or more nucleoli, a high nuclear/cytoplasmic ratio, and nongranular cytoplasm. They show nuclear labeling with tritiated thymidine.

(2) Promyelocytes differ from myeloblasts by the appearance of azurophilic granules in the cytoplasm.

(3) Neutrophilic myelocytes differ from promyelocytes by the appearance of specific neutrophilic granules. The nuclei show some chromatin condensation, and nucleoli are not as prominent as in the preceding stage. On Romanowsky-stained smears, the cells have round, oval, or flattened nuclei without indentation; however, this criterion was superseded when indented nuclei showed labeling with tritiated thymidine.¹³

(4) Neutrophilic metamyelocytes differ from myelocytes by the appearance of a nuclear indentation and absence of nuclear labeling with tritiated thymidine.

(5) Neutrophilic bands differ from metamyelocytes in that the nuclear indentation is more than half the diameter of a hypothetical circle and the nucleus has parallel sides.

(6) Segmented neutrophils differ from bands in that the nucleus is divided into lobes separated by a thin filament with no visible nuclear chromatin between the two sides.

Fc-IgG receptors. Fc-IgG receptors (FcR) were detected by rosette formation with group O type Rh₁Rh₂ erythrocytes sensitized with human anti CD (Ripley) serum (EA_{hm}).^{14,15} Rosettes of sensitized erythrocytes attached to leukocytes were evaluated in wet preparations and on stained smears prepared with a Larc spinner (Corning Glass Works, Medfield, MA). The percentage of positive cells at each stage of differentiation was evaluated by morphology from the smears. A positive cell was considered to be a leukocyte with one or more attached erythrocytes. Anti-Leu-11b (Becton Dickinson, Mountain View, CA) was also used to study the Fc receptor.¹⁶ Immunogold was used as the detection system (Geometric Data, Wayne, PA). Twenty microliters of 10⁶ leukocytes was mixed with 20 μL of 0.5% paraformaldehyde and 5 μL of anti-Leu-11b. The suspension was incubated at 5 °C for 15 minutes. The paraformaldehyde was necessary in this initial step to prevent phagocytosis of the colloidal gold by the phagocytes. After washing, 20 μL of the colloidal gold reagent was added and incubated at room temperature for 15 minutes. Cells were washed, 5 μL of autologous EDTA plasma was added, and the cells were incubated for 20 minutes at 37 °C. Two microliters of 30% bovine albumin was then added, and push smears or cytocentrifuged slides were prepared and stained. Positive cells have dark blue-black particles visible on the cell surface.

Complement receptors. Complement receptors were assayed with MoAbs (Becton Dickinson): anti-CR₁ (C3b, C4b receptor), anti-CR₃/anti-Leu-15 (C3bi receptor). The method is similar to that described for FcR using MoAbs and immunogold. The classification of the different stages of differentiation was easily evaluated from Romanowsky-stained smears.

Phagocytosis. Neutrophil phagocytosis was evaluated using *S. aureus* (ATCC strain 25933) as the test particle. The bacteria were

opsonized by adding normal pooled human AB serum for 30 minutes at 37 °C. Live bacteria were used to determine the percentage of phagocytic neutrophils, since this results in optimal phagocytosis.¹⁷ Bacteria that were heat killed at 60 °C for one hour were used to evaluate differences in the number of particles ingested per phagocyte to eliminate intracellular bacterial multiplication as a variable. In the reaction mixture the concentration of the specific neutrophilic cell-type being evaluated was 1,000/ μL , the bacteria to leukocyte ratio ranged from 20:1 to 50:1, the final test volume was 0.5 mL, and the suspending medium was pooled human AB serum. The leukocyte-bacterial mixtures of each of the fractions were incubated for one hour at 37 °C, with constant agitation, in polystyrene test tubes. Then the leukocytes were labeled with tritiated thymidine for 60 minutes. Smears were made with a Larc spinner. All smears were stained with Giemsa solution. Five hundred cells at each stage of differentiation, except for myeloblasts and progranulocytes, were evaluated for determining the percentage of phagocytic cells, and 50 phagocytic cells at each stage were evaluated for the number of ingested particles per phagocyte.

Microbial killing. Bacterial killing was assayed by a modification of Cline's technique using *S. aureus*.¹⁸ Mixtures of bacteria with the specified cell type were incubated at a ratio of 20:1 for 30 minutes at 37 °C in a test tube with continuous agitation. After phagocytosis, the cells were washed. A 0.5-mL solution of McCoy's medium with 30% AB serum and tritiated thymidine (New England Nuclear Corp, Boston, 60 to 80 Ci/mmol) was added to 1.0 mL of the cell suspension. The final mixture contained 3 μCi of tritiated thymidine. Cells were incubated for 30 minutes at 37 °C for labeling, and slides were prepared for autoradiography. The total number of intracellular organisms and the number of organisms associated with grains were counted in 50 phagocytic cells of each neutrophilic cell type. The percentage of viable bacteria was calculated from the percentage of bacteria labeled, corrected for 100% labeling.¹⁸

Autoradiography. Cells were labeled with tritiated thymidine of high specific activity (60 to 80 Ci/mmol) for the labeling of both leukocytes and bacteria, as described above. Autoradiography was done as described by Durie and Salmon.¹⁹ Smears were stained through the emulsion with Giemsa solution.

Nitroblue tetrazolium dye reduction. The respiratory burst was evaluated by a modification of the cytochemical technique of Park et al.²⁰ Cells were suspended in 0.5 mL of AB serum to which 0.05 mL of 100 $\mu\text{g/mL}$ of Bacto lipopolysaccharide (Difco, Detroit) was added. A 0.1-mL aliquot of this mixture was added to an equal volume of 0.1% nitroblue tetrazolium (Sigma, St. Louis). A drop of the mixture was added to a glass slide, and the cell suspension was covered with a coverslip that was sealed and then incubated at 37 °C for 30 minutes. In two experiments cells were examined with phase and light microscopy to evaluate both the stage of cellular maturation and dye reduction. At least 200 cells were counted in each fraction. In another experiment we attempted to improve the identification of the stage of cellular differentiation by vital staining with acridine orange (Fisher Scientific, Fair Lawn, NJ). Freshly prepared acridine orange (AO) solution (14.0 mg/100 mL in HBSS, pH 7.2) was added to the cells, mixed, and stained for 45 seconds at room temperature. The AO-stained cells were 98% viable. The cells were then suspended in 0.5 mL of AB serum to which 0.05 mL of endotoxin was added, and the remaining procedure was identical to that described previously. Nitroblue tetrazolium (NBT) dye reduction was evaluated by light microscopy and cell morphology by both light and fluorescent microscopy.

Locomotion. Chemotaxis was evaluated in vitro by the agarose technique.^{21,22} The total inoculum of the desired cell type was 10⁵. The chemotactic well was filled with thawed fresh-frozen AB serum. Interaction of the agarose with the serum generates complement-derived chemotactic factors, eg, C5a. Cells were incubated for five

hours at 37 °C in 5% CO₂ atmosphere with humidity and were stained with Giemsa solution. Chemotaxis was quantitated by counting all the leukocytes of the desired cell type that had migrated out of the well. The cells were identified by light microscopy under oil immersion ($\times 1000$).

Electron microscopy. Leukocytes were fixed in 3% glutaraldehyde made up in 0.1 mol/L phosphate buffer, postfixed in osmium tetroxide, dehydrated in alcohol, and embedded in Spurr's epoxy resin. Sections were cut on a Sorvall MT2-B ultramicrotome and mounted on uncoated 200-mesh grids. A 5% aqueous uranyl acetate solution followed by lead citrate increased contrast. The grids were lightly carbon coated and examined with the Hitachi HU-12 electron microscope. In one experiment, phagocytic myeloid cells were classified ultrastructurally using myeloperoxidase as a marker for primary granules. After phagocytosis cells were fixed in cold 3% glutaraldehyde (pH 7.2), washed, and reacted with diaminobenzidine (1 mg/mL) in 0.05 mol/L Tris buffer containing 0.03% hydrogen peroxide for two hours in a dark room. There was no postfixation in osmium tetroxide or staining with uranyl acetate or lead citrate.

RESULTS

Leukocyte fractions. Neutrophilic leukocytes were separated from the bone marrow or blood on the basis of size and density using gradient-density separation and counterflow centrifugal elutriation, which provided sufficient numbers of cells for functional testing. Mean leukocyte viability of the fractions used for testing ranged from 95% to 100%. We were able to obtain fractions of segmented neutrophils from the blood essentially free of contamination from band neutrophils and fractions of band neutrophils from the bone marrow essentially free of segmented neutrophils. The fraction of immature cells from the bone marrow contained a mean of 60% intermediate (myelocytes and metamyelocytes) neutrophils and 3.9% promyelocytes. It also contained a moderate number of band neutrophils. The percentages of each cell type in each fraction are shown in Table 1. Since the enriched fractions were not entirely pure, techniques for the measurement of neutrophil function were selected that allowed cytologic evaluation.

Fc-IgG receptors. The percentage of EA rosettes in wet preparations and stained smears were in close agreement. In stained smears, sensitized erythrocytes that attached to Fc

Myelocyte	42
Metamyelocyte	55
Band neutrophil	78
Segmented neutrophil	82

*Mean values (n = 2 experiments).

†Too few cells seen for evaluation.

receptors on leukocytes were closely applied, frequently molded, and often showed fine hairlike projections extending from the erythrocyte to the leukocyte. The earliest cells, in which Fc receptors were detected, were promyelocytes. Fc-positive cells reached their optimal expression at the band and segmented neutrophil stages (Table 2). Results using the rosette technique differed from those obtained using anti-Leu-11b. In two experiments using the MoAb, only the most mature neutrophils were Leu-11b positive: 82% segmented neutrophils, 40% band neutrophils, 3% neutrophilic metamyelocytes, 0% neutrophilic myelocytes, 0% promyelocytes, 0% myeloblasts.

Complement receptors. Monoclonal antibodies to complement receptors detected CR₁ and CR₃ on neutrophilic leukocytes. These receptors appeared later in development than FcR. Complement receptors were occasionally detected on promyelocytes. CR₃ appeared first and was the dominant receptor in later stages of development. CR₃ was first detected at the promyelocyte stage. A marked increase in expression occurred in cells of the nondividing maturation pool. Thus metamyelocytes had a sixfold increase in positive cells compared with myelocytes. Greater than 90% of band and segmented neutrophils reacted with anti-CR₃ (anti-Leu-15). Results are summarized in Table 3.

Phagocytosis. Even a rare blast had the capacity to phagocytize, and the number of phagocytic cells gradually increased as the cells matured. The phagocytic capacity of immature cells was confirmed by electron microscopy (Fig 1). There was a sharp increase in phagocytic cells as cells entered the nondividing maturation pool. Thus there were more than twice as many phagocytizing metamyelocytes as myelocytes. Peak phagocytosis was reached at the band stage. In two experiments mean values for the percentage of phagocytic cells were: myeloblasts <1%, promyelocytes 10%,

Fig 1. Electron micrographs of granulocyte precursors obtained from the bone marrow of normal subjects. (A) This cell is consistent with a progranulocyte. It has an ovoid nucleus with euchromatin and two nucleoli (Nu). There are numerous electron dense cytoplasmic granules (g). The Golgi (Go) zone is large. Adjacent to the Golgi is a phagocytized bacterium, *Staphylococcus aureus* (arrow). The microorganism is surrounded by an electron-dense material that may represent plasma protein opsonins. No phagolysosome formation is evident. (Uranyl acetate, lead citrate, original magnification $\times 12,400$, current magnification $\times 8,060$.) (B) Immature granulocyte. The cell contains numerous mature primary peroxidase-positive electron-dense granules, has a slightly indented nucleus and prominent nucleolus, and lacks peroxidase in the endoplasmic reticulum. This cell is a "hiatal" cell in transition between a promyelocyte and myelocyte. A bacterium (arrow) has been phagocytized. It is in a vacuole to which numerous peroxidase-positive granules are adherent, forming an incipient phagolysosome. (Diaminobenzidine, original magnification $\times 13,200$; current magnification $\times 8,580$.)

myelocytes 34%, metamyelocytes 84%, band neutrophils 99%, and segmented neutrophils 99%. The phagocytic capacity (ie, bacteria/phagocyte) of each cell type showed the same trend as percent phagocytosis. Too few phagocytic cells were seen at the myeloblast and promyelocyte stage for a meaningful comparison with other stages of maturation. There was a marked increase of phagocytic capacity as cells entered the nondividing maturation pool. Mean values for two experiments showed that myelocytes ingested seven bacteria/cell, metamyelocytes 14/cell, band neutrophils 36/cell, and segmented neutrophils 38/cell.

Stimulated NBT dye reduction. The techniques used in these experiments allowed us to identify each morphological stage of differentiation showing nitroblue tetrazolium dye reduction. The results were striking. Only band and segmented neutrophils showed a "respiratory burst," as evalu-

ated with the cytochemical technique. Also there was a significant difference in NBT reduction between band and segmented neutrophils ($p < 0.05$). Mean values in three experiments were: myeloblasts 0%, promyelocytes 0%, intermediate neutrophils (myelocytes and metamyelocytes) 1%, band neutrophils 57%, and segmented neutrophils 98%.

Microbial killing. Two normal cell donors were tested to evaluate bacterial killing. Both the percentage of bacteria killed by phagocytic cells of each cell type and the total number of bacteria killed by equivalent numbers of leukocytes of each cell type were determined. Two few phagocytic promyelocytes were seen for a statistical comparison of bacterial killing with other cell types; however, the few phagocytic promyelocytes seen showed only modest killing, and two thirds of the bacteria survived intracellularly. Since promyelocytes did not reduce nitroblue tetrazolium, all kill-

Fig 2. Bactericidal activity of developing neutrophils. Following ingestion, bacteria-leukocyte mixtures were exposed to tritiated thymidine. Autoradiographs show a progressive increase in bactericidal activity with progressive differentiation of the neutrophil. (A) Myelocyte: Several grains on the nucleus indicate active incorporation of thymidine. The cytoplasm shows several labeled bacteria. (B) Metamyelocyte: The nucleus is not labeled. There are numerous ingested bacteria, some showing labeling. (C) Band neutrophil: Numerous intracellular dead (unlabeled) bacteria and a few labeled bacteria. (D) Segmented neutrophil: Numerous intracellular bacteria with only a single labeled organism. Original magnification $\times 500$.

ing was attributed to oxygen-independent mechanisms. Each successive stage of neutrophil differentiation showed increased bacterial killing with decreased numbers of viable intracellular bacteria (Fig 2). Myelocytes were poor killers, and as many as 48% of the ingested bacteria were viable. As in the promyelocyte, no mechanism for oxidative killing was demonstrated. Metamyelocytes also did not reduce NBT but killed a substantial number of ingested organisms by oxygen-independent mechanisms. A mean of only 11% of ingested organisms were viable after interacting with metamyelocytes. This cell type demonstrates the competence of oxygen-independent killing mechanisms. Band neutrophils killed more microorganisms both relatively and quantitatively, containing a mean of 8% viable intracellular bacteria. This cell type reduced NBT. Thus killing involved both oxygen-independent and oxygen-dependent mechanisms. Segmented

neutrophils were the most effective bactericidal cells. Only 5% of the bacteria were viable after ingestion. As shown in Table 4, differences in the bactericidal capacity of each cell type are much greater when the total number of bacteria killed by equivalent numbers of leukocytes are compared.

Chemotaxis. Chemotaxis was a later manifestation of functional maturity. Essentially no chemotaxis was observed except in band and segmented neutrophils. Band neutrophils showed approximately half the activity of segmented neutrophils. In two experiments the mean chemotactic scores for the three fractions analyzed were intermediate neutrophils (myelocytes, metamyelocytes) 6, band neutrophils 424, and segmented neutrophils 900 (Fig 3).

DISCUSSION

The sequence of development of the functional properties of the neutrophil during differentiation has not previously been determined. Neutrophils must have the biological functions needed to eradicate microbes. In the inflammatory process a distinct sequence of events occurs. Locomotion, diapedesis, and chemotaxis precede phagocytosis. Ultimately the internal killing mechanisms of the cell destroy the microbe. During differentiation the functional properties of the neutrophil are acquired sequentially. Our data show that phagocytosis is acquired prior to the functions, followed by oxygen-independent microbial killing, whereas both oxygen-dependent microbial killing and chemotaxis are late manifestations of functional differentiation. According to our data the relative activity of each neutrophilic cell type for each function is shown in Fig 4.

Fc and complement receptors are acquired early in differentiation.⁴ Both are important in immune phagocytosis. Interaction of Fc receptors with opsonins trigger second messages, promoting both phagocytosis and superoxide generation.²³ Our results show that Fc receptors appear at least as early as the promyelocyte stage. Results of the rosette technique using sensitized erythrocytes differed from those of the MoAb Leu-11b. The former must be considered the reference method for the qualitative detection of Fc receptors. There are several possible explanations for the differences. The absence of Leu-11b on immature granulocytes may indicate that further molecular modeling of Fc receptors occurs at the band neutrophil stage. It is also possible that the antigenic determinant Leu-11b is not part of the Fc receptor even though anti-Leu-11b inhibits the function of the receptor. Another explanation is that the FcR epitope detected by anti-Leu-11b is not critical for the binding of IgG-sensitized erythrocytes. In murine neutrophils it has been proposed that Fc receptors appear on the cell membrane before the cellular acquisition of phagocytosis.²⁴ Murine myelocytes were the earliest cells to acquire Fc receptors; however, only segmented neutrophils or neutrophils with O-ring nuclei were phagocytic. Altman and Stossel studied phagocytosis in developing human neutrophils, and they did not observe phagocytosis by promyelocytes.²⁵ In our experiments human neutrophils showed phagocytosis as early as the promyelocyte stage, and phagocytic capacity lagged slightly behind but paralleled the acquisition of Fc receptors. We used enriched fractions of bone marrow rather than a mixture of

A rare myelocyte and metamyelocyte (inset) are seen migrating toward the chemotactic attractant. (B) Band neutrophil fraction. A moderate number of band neutrophils migrate toward the chemotactic attractant. (C) Segmented neutrophils. Numerous segmented neutrophils migrate toward the chemotactic attractant.

all bone marrow leukocytes. This enabled us to standardize the ratios for each cell type and to diminish the competitive effect of more actively phagocytic cells, thereby allowing leukocytes such as promyelocytes to express their full phagocytic potential. Enriched fractions may simply allow more promyelocytes to be evaluated experimentally. We also used a different particle, live bacteria rather than opsonized albumin or lipopolysaccharide-coated paraffin oil droplets. The type of particle and the method of preparation of the particle are critical. For example, in our experiments we noted that promyelocytes phagocytized opsonized live bacteria more readily than opsonized dead bacteria. This is consistent with the observation that human segmented neutrophils distinguish between viable and nonviable bacteria and preferentially ingest live organisms.¹⁷ The best evidence in humans that Fc receptors are acquired by granulocytes

prior to the capacity for phagocytosis comes from studies with human myeloid leukemic cell strains.⁹ Whereas some leukemic strains show prominent EA_{hu} rosettes and little or no phagocytosis, no Fc receptor-negative myeloid-leukemic strains have shown phagocytosis. Thus human leukemic cells clearly demonstrate that the acquisition of Fc receptors precedes phagocytosis.

In addition to FcR, complement receptors also promote phagocytosis. Ligands derived from the third component of complement (C3) are the principal opsonic forms of complement. There are two complement receptors on neutrophils that react with C3 opsonins: CR_1 and CR_3 . These receptors react synergistically with Fc receptors to promote phagocytosis.^{23,26} They appear at a later stage of development than Fc receptors and phagocytosis and are not overtly expressed until the myelocyte/metamyelocyte stage. Once complement receptors are acquired, phagocytosis is enhanced. It is teleologically satisfying that the receptor for the predominant opsonic species C3bi appears prior to other complement receptors.

The next function acquired by differentiating neutrophils was microbial killing. The labeling technique coupled with the NBT test can be used to assess the contribution of both oxygen-independent and oxygen-dependent bactericidal mechanisms. It is well established that the biochemical basis of NBT reduction in normal human neutrophils is due to superoxide generation and that cytochemical NBT reduction is an expression of the respiratory burst.²⁷ Phagocytic promyelocytes killed few bacteria. Promyelocytes have no oxidative killing; however, it also appears that their oxygen-independent bactericidal mechanisms are inoperative. Promyelocytes have primary granules that contain lysosomal enzymes, lysozyme, and cationic bactericidal proteins. Thus the armamentarium for oxygen-independent killing is present. It is possible that suboptimal phagolysosome formation

Fig 4. Schematic representation of the relative activity of neutrophil functions at various stages of neutrophil differentiation.

or absence of secondary granules, which contain bactericidal substances such as lactoferrin, accounts for impaired nonoxidative killing. Like promyelocytes, neither myelocytes nor metamyelocytes showed a respiratory burst; however, both cell types killed bacteria. The importance of neutrophilic nonoxidative microbial killing has been thoroughly reviewed by Spitznagel.²⁸

Oxygen-dependent bacterial killing is a late manifestation of functional differentiation. Only band and segmented neutrophils showed a substantial respiratory burst. Segmented neutrophils had significantly more activity than band neutrophils. These results are similar to the observations of Zakhireh and Root.²⁹ Since oxygen-independent and oxygen-dependent antimicrobial mechanisms are synergistic and overlapping, it may not be possible to assess their relative roles in band and segmented neutrophils.

Chemotaxis is also a late manifestation of functional differentiation. Previous studies on immature myeloid leukemic cells indicated that random motility was expressed in the absence of chemotaxis.⁹ Further modulation of the cell is necessary for chemotaxis. This may relate to the molecular modeling of C5a receptors, the translation of chemotactic stimuli, or the cytoskeleton.^{30,31} Studies using the human promyelocytic leukemia HL60 cell line as a model of myeloid

differentiation show that the binding of chemotactic factors to receptor sites alone is not sufficient for chemotaxis.³² In our study chemotaxis was rarely observed except in band and segmented neutrophils. The latter had twice the activity of band neutrophils. Thus chemotaxis is expressed late and represents a terminal stage of functional differentiation.

We have studied a fundamental aspect of leukocyte differentiation, neutrophil functional differentiation. According to these studies we propose the following sequence for the functional differentiation of the neutrophil: Fc receptors → immune phagocytosis → complement receptors → oxygen-independent microbial killing → oxygen-dependent microbial killing → chemotaxis.

ACKNOWLEDGMENT

We gratefully express our appreciation to Dr Jack M. Layton for his continuous encouragement and support, to Dr Claire Payne and Douglas W. Cromey, MS, for their help with the electron microscopy, to Dr Brian Durie for extending his laboratory facilities for the autoradiography, to Yvette Frutiger, BA, for developing the autoradiographs, to Dr Douglas W. Huestis for his thoughtful review of the manuscript, and to Linda Boyle and Isabel Chacon for preparation of the manuscript.

F-Actin Content of Neonate and Adult Neutrophils

By Ann Hilmo and Thomas H. Howard

We utilized flow cytometric analysis of NBDphalloidin-stained cells to measure F-actin content, expressed as fluorescent channel numbers, and we compared the microfilamentous cytoskeletal organization in neutrophils from healthy neonates (36 to 38 weeks gestational age) and adults. Basal F-actin content in neonate cord blood neutrophils is higher than that of adults. The elevation is intrinsic to the cell and not related to parturition because basal F-actin content of neonatal cells obtained by venipuncture (days 1 to 8 of age) is also elevated (38 ± 10 , $N = 15$) when compared to adults (21 ± 7.0 , $N = 27$). The rate of N-formyl-methionyl-leucyl-phenylalanine (fMLP)-induced actin polymerization is similar in adult and neonatal neutrophils and is maximal by 30 to 45 seconds at 25 °C. Adult, neonatal cord, and neonatal venipuncture neutrophils increase F-actin content to a similar extent following 0.5 $\mu\text{mol/L}$ fMLP activation (52 ± 18 , $N = 27$; 58.7 ± 18 , $N =$

18 ; 51.5 ± 7.0 , $N = 15$, respectively). However, the relative increase in F-actin content following fMLP activation is much greater in adult (2.37-fold) than neonatal neutrophils (1.28-fold). This difference is due to the elevated basal F-actin content of neonatal cells. Comparison of distribution of F-actin content among basal, neonatal neutrophils reveals two subpopulations of neutrophils with respect to F-actin content—approximately 25% with F-actin content similar to that of adult neutrophils and 75% with F-actin content greater than that of adult cells. Following fMLP activation, the subpopulations disappear. The results suggest that abnormalities in microfilamentous cytoskeletal organization of neonatal cells may, in part, be responsible for decreased chemotactic response of neonatal neutrophils.

© 1987 by Grune & Stratton, Inc.

BACTERIAL INFECTION is a leading cause of mortality among newborns in the United States.¹ Increased susceptibility of the neonate to bacterial infection is due in part to the immaturity of both the cellular and the humoral immune system.² Defective mobilization of neutrophils into inflammatory sites was one of the earliest cellular abnormalities documented in neonates.³ An *in vitro* corollary of the ineffective mobilization of neutrophils is decreased chemotactic responsiveness of the neonatal neutrophil. Numerous investigators demonstrated decreased chemotactic response of neonatal neutrophils as compared to adult neutrophils.³⁻⁷ Others have suggested that neutrophils from neonates are defective in random locomotion, and critical studies that analyzed both rate and orientational elements of the chemotactic response show that both are defective in neonatal neutrophils as compared to adult neutrophils.⁵

The search for an explanation of the decreased motility of neonatal neutrophils has recently focused on the cytoskeleton of the cell. Studies by Cheung and Miller⁸ showed that the neonatal neutrophil is less deformable than the adult neutrophil. Since cellular deformability is a characteristic of the membrane and the cytoskeleton and since evidence indicates that the orientational element of neutrophil locomotion requires an intact microtubular cytoskeleton,⁹ Anderson and co-workers studied the microtubular cytoskeleton of the neonatal neutrophils.¹⁰ Their studies show that when compared to adult neutrophils, neonatal cells contain fewer, shorter, and more disoriented microtubules than adult cells. These studies suggest that the defective orientational response of neonatal neutrophils may be related to defective organization of the microtubular cytoskeleton. To date the force-generating element of the cell, the microfilamentous cytoskeleton, has not been examined in the neonatal neutrophil.

The molecular composition of the microfilamentous cytoskeleton in phagocytes is clearly described by Southwick and Stossel.¹¹ The major component of this cytoskeleton is actin. Actin is a 43-kD globular protein that can condense to form filaments called F-actin. F-actin can serve either a force-generating role by interacting with myosin or a structural

role through crosslinks formed with other structural proteins like actin-binding protein.¹² Until recently quantification of the mass of F-actin in cells was difficult and required large numbers of neutrophils. Our laboratory recently described a simple, quantitative method for measuring F-actin content. The method is based upon flow cytometric analysis of neutrophils stained with NBDphalloidin—a fluorescent probe that binds specifically to F-actin.^{13,14}

In the studies presented we quantify the F-actin content and compare the microfilamentous cytoskeletal organization of neutrophils from neonates and adults. Our results show that the basal F-actin content of neonatal neutrophils is significantly higher than that of adult neutrophils and that chemotactic peptide-induced actin polymerization is significantly less in neonate than in adult neutrophils. Also, unlike adult neutrophils, neonatal neutrophils are composed of two subpopulations of cells with respect to basal F-actin content. Our results suggest that differences in the microfilamentous cytoskeleton in neonatal and adult neutrophils may relate to the differences in motility and chemotactic responsiveness of neonate and adult neutrophils.

MATERIALS AND METHODS

Preparation of leukocytes. Cord blood was obtained after delivery of healthy term neonates (gestational age 37 to 42 weeks by Dubowitz). After informed consent was obtained, venous blood was

collected from healthy adults and healthy term neonates (gestational age 36 to 42 weeks by Dubowitz) between 1 and 8 days of age. Whole blood was drawn into plastic syringes with EDTA anticoagulant. Samples were centrifuged in plastic tubes ($900 \text{ g} \times 3 \text{ minutes}$) with a Beckman (Norcross, GA) TJ6 centrifuge. Plasma was removed and cells were suspended in phosphate buffered saline (PBS) pH 7.15 and centrifuged ($1,800 \text{ g} \times 10 \text{ minutes}$). Supernatant was discarded, and the buffy coat, which contains mixed leukocytes, was aspirated and transferred into plastic tubes. Red cells were hypotonically lysed in distilled water for 45 seconds and washed once in PBS. Leukocytes were resuspended in Hanks'/HEPES balanced salt solution¹³ at a concentration of 4×10^6 cells/mL. All steps of cell preparation were completed at 22°C .

Assay of F-actin content. The leukocyte suspension (0.5 mL) was warmed to 25°C . Samples were exposed to 0.5 mL of either dimethyl sulfoxide (DMSO) (0.01 vol % final concentration) or the chemotactic peptide, N-formyl-methionyl-leucyl-phenylalanine (fMLP; Sigma, St. Louis; 5×10^{-7} mol/L final concentration) for the indicated period of time. The fMLP was dissolved in DMSO. After indicated period of time with DMSO or fMLP, cells were fixed with 3.7% formalin for 15 minutes at 25°C , stored overnight at 4°C , and then permeabilized with lysophosphatidylcholine, stained with NBDphalloidin, and analyzed by fluorescence-activated cell sorter. Time from collection of blood to fixation of cells never exceeded five hours.

Quantification of F-actin. Formalin-fixed cells from buffy coat cells were permeabilized with lysophosphatidylcholine and stained with NBDphalloidin as previously described.¹⁴ The sample was filtered with a $50\text{-}\mu\text{m}^2$ nylon mesh and analyzed on a Coulter C flow cytometer. Mixed leukocytes were analyzed for forward light scatter and 90° light scatter to generate a dot plot. As previously described for permeabilized cells,^{15,16} neutrophils are the group of leukocytes on the dot plot with greatest 90° and forward light scatter. Sorting of cells in this gated population revealed $>93\%$ neutrophils on samples from neonates and adults. Cytospin preparations of the gated cells included only bands and segmented forms in both adults and neonates as previously described.^{15,16} The relative proportions of bands and segmented forms among neutrophilic cells from both sources were similar (adults $N = 8$; bands $7.3 \pm 5\%$, the remainder segmented; neonates $n = 8$, bands 9.0 ± 4.3 , the remainder segmented; a rare metamyelocyte in both cases).

After setting the gate for neutrophil population, the log- and linear-scaled fluorescence histograms from 10,000 neutrophils were determined (Argon Laser 5W, excitation at 488 nm, and emission at ≥ 520 nm with a long-pass filter). Fluorescence gain and PMT voltage were identical for all samples. The Coulter C flow cytometer yields values that include mean fluorescence channel number for the 10,000 cell population. F-actin content is expressed as mean fluorescence channel number from linear-scaled histograms. Basal F-actin is defined as mean fluorescence channel number of cells exposed to DMSO for 60 seconds and is identical to cells exposed to buffer for 60 seconds. Neither basal nor fMLP-activated F-actin content was affected by mode of delivery, presence or absence of labor, or expiration of time (one to three hours) before separation of leukocytes.

For experiments in which cumulative, normalized histograms are shown, three-decade log fluorescence histograms were recorded concurrent with the linear histograms. In each case the log fluorescence histograms included all cells observed on the linear histogram, and no additional outliers were present. The peak fluorescence channel always occupied a position approximately two thirds of the way through the second decade of the three-decade scale. The data was normalized by tracing log fluorescence histograms of samples onto tracing paper, marking the horizontal axis at 0.5-cm intervals, and dividing the histograms into constituent portions by placing

vertical lines at 0.5-cm intervals. Then, the total area of each histogram was determined and assigned a value of 100%. Next, the area of each constituent portion of each histogram was determined and expressed as a percentage of the whole histogram area. The percentage of histogram area in a 0.5-cm interval reflects the percentage of cells in that interval. The data on several histograms were cumulatively expressed by determining the mean percent ± 1 SD of cells in the constituent portions of N histograms. The areas were measured in triplicate with a GP-650 sonic digitizer from Science Accessories (Highland, NY).

RESULTS

Comparison of basal F-actin content. The basal F-actin content of neonate and adult neutrophils was compared by flow cytometric analysis as described in "Methods." Briefly, subgroups of NBDphalloidin-stained buffy coat cells are characterized by forward and 90° light scatter, gated for neutrophils, and the F-actin content expressed as the mean fluorescence channel number as determined from the linear-scaled histogram of 10,000 neutrophils. The mean fluorescence channel number is the mean for the entire population regardless of whether subpopulations are present or absent.

As shown in Fig 1, the basal F-actin content of neonatal cord blood neutrophils (35.8 ± 15 [$N = 18$]) is significantly higher ($P < 0.001$) than that of adult neutrophils (21.0 ± 7.0 [$N = 27$]). Basal F-actin content of neonate neutrophils obtained by venipuncture is similar to that of cord blood neutrophils (38 ± 10 [$N = 15$]) and higher than adult cells ($P < 0.001$). This result indicates that the elevated basal F-actin content is characteristic of neonate cells and is not a transient abnormality related to parturition. Basal F-actin content of cord samples was similar for neonates delivered vaginally or by caesarean section and was not affected by anesthesia (local v spinal) utilized (data not shown).

Comparison of fMLP-induced actin polymerization. Exposure of adult neutrophils to chemotactic stimuli, such as fMLP, results in rapid polymerization of actin at 25°C . Maximal F-actin content is noted 45 to 60 seconds after activation with fMLP concentrations greater than 10^{-8}

Fig 1. Comparison of basal F-actin content in adult and neonatal neutrophils. Shown are the mean F-actin content ± 1 SD from N number of samples of adult, neonatal cord, and neonatal venipuncture (VP) neutrophils. F-actin content is expressed as mean fluorescence channel number determined by flow cytometric analysis of NBDphalloidin-stained cells. Each dot is one individual.

mol/L.¹⁴ The rapid initial polymerization is followed by a slower depolymerization during five to ten minutes.^{14,17} We compared the fMLP-induced polymerization of actin in neonate and adult neutrophils. Results are shown in Fig 2. Activation of neonatal and adult neutrophils with 0.5 μ mol/L fMLP induces actin polymerization. The time course and rate of fMLP-induced change in F-actin content are similar for adult and cord neutrophils. Both are maximal at ≥ 30 seconds. However, greater variability of polymerization in neonate cells is reflected in the larger standard deviations for neonate than adult cells.

Comparison of F-actin content of neonate and adult neutrophils exposed to fMLP for 60 seconds shows that the maximal F-actin content of fMLP-activated neutrophils from adults (52 ± 18 [N = 27]), neonatal cord blood (58.7 ± 18 [N = 18]), and neonatal venipuncture (51.5 ± 7 [N = 15]) is similar. Since maximal extent of fMLP-induced actin polymerization is similar for adult and neonate neutrophils and since the basal F-actin content of neonate neutrophils is greater than that of adult cells, the fMLP-induced change in relative F-actin content is more heterogeneous but significantly less in neonatal neutrophils (adult 2.76 ± 0.67 , N = 24; cord 1.71 ± 0.59 , N = 17 [$P < 0.001$]; neonate VP 1.28 ± 0.24 , N = 14 [$P < 0.001$]; see Fig 3).

Evidence for subpopulations of neonatal neutrophils. In addition to yielding the mean F-actin content for a population of neutrophils, flow cytometric analysis of NBDphalloidin-stained neutrophils generates a fluorescence histogram that depicts the distribution of F-actin content among constituent cells of a population.^{13,17} In general, the values for F-actin content among 10,000 adult neutrophils are more homogeneously distributed than those from neonates. Values in neonatal neutrophils are broadly spread, and in most cases histograms reveal the presence of two populations of cells with respect to F-actin content. One population is adultlike, the other population has elevated F-actin content. The relative proportions of cells with adultlike F-actin content are variable from one neonate to another. Following fMLP-activation, the F-actin content among neonate and adult

Fig 2. Comparison of fMLP-induced actin polymerization in adult and neonatal neutrophils. Shown are F-actin content at indicated time after exposure of adult (●—●) and neonatal (○—○) neutrophils to 0.5 μ mol/L fMLP. Values are mean $\pm$ 1 SD from five trials.

Fig 3. Comparison of fMLP-induced increase in relative F-actin content in adult and neonatal neutrophils. Relative F-actin content is ratio of F-actin content at 60 seconds after 0.5 μ mol/L fMLP/basal F-actin content. Shown are mean relative F-actin content $\pm$ 1 SD from N number of samples of adult, neonatal cord, neonatal venipuncture (VP) neutrophils. Each dot is one individual.

neutrophils is similar, and both are described by more normal distributions.

Comparisons of normalized histograms from larger numbers of adult, neonate cord, and neonate venipuncture samples confirm the presence of subpopulations of neonatal neutrophils. Figure 4 shows the comparison of normalized, log-scale fluorescence histograms of F-actin content in neutrophils from ten adults, 14 neonate cord, and 15 neonate venipuncture samples. Nonactivated neonatal neutrophils from cord or venipuncture samples contain two subpopulations of neutrophils. In contrast, adult neutrophils are represented as a single, normal distribution of neutrophils with respect to F-actin content. On average, approximately 25% of neonate neutrophils have a basal F-actin content similar to

Fig 4. Distribution of basal F-actin content among adult and neonatal neutrophils: cumulative, normalized data. Histograms from ten adults (○—○), 14 neonatal cord (Δ — Δ), and 15 neonatal venipuncture (●—●) samples were normalized as described in "Materials and Methods." Shown are mean percentage $\pm$ 1 SD of neutrophils with F-actin content at 0.5-cm intervals along the log-F-actin histogram. Values are statistically significantly different from adult values at the indicated (*) points.

that of adult neutrophils. The F-actin content of the remaining 75% of neonatal cells is significantly higher than that of adult cells. However, note that in individual patients the relative proportion of cells with elevated basal F-actin content is highly variable (range 48% to 95%, mean 75%).

Comparison of normalized histograms for F-actin content following fMLP activation shows that maximal F-actin content in adult and neonatal neutrophils is similar and more normally distributed at values slightly higher than those of basal adult cells and either of the subpopulations of neonatal neutrophils (Fig 5). Of interest during fMLP-induced actin polymerization, the histograms for both adult and neonate cells broaden within five seconds of fMLP addition. At no time do adult cells contain two distinct subpopulations, and subpopulations among neonatal cells are only apparent in nonactivated cells (data not shown). This result suggests, but does not prove, that the subgroups of neonate cells differ only in the extent of polymerization in the basal cell and do not differ in their kinetics of polymerization.

DISCUSSION

When compared to adult neutrophils, motility of neutrophils from neonates is abnormal. The abnormalities include defects in basal locomotion,^{5,6} chemokinesis,^{5,6} chemotaxis,³⁻⁷ orientational response,¹⁰ concanavalin A (Con A) capping,^{18,19} and abnormally decreased elasticity⁸ of neonatal cells. Anderson et al¹⁰ showed that the microtubular cytoskeleton of neonatal neutrophils is significantly different from that of adult neutrophils. In the presence of chemotactic factors, adult and neonatal neutrophils increase the number, length, and mass of microtubules.¹⁰ However, under similar conditions of activation, neonatal neutrophils contain fewer microtubules of shorter length than do adult neutrophils. Anderson¹⁰ suggests that the differences in microtubu-

lar organization may underlie the known defects in motility of neonatal neutrophils. However, organization of the microfilamentous cytoskeleton in neonatal neutrophils has not been studied. This report quantitatively describes the organization of microfilamentous cytoskeleton in neonatal neutrophils.

In these studies we compare the basal and fMLP-activated microfilamentous cytoskeletons of neonatal and adult neutrophils as reflected by the filamentous actin (F-actin) content of cells. The mean F-actin content and the distribution of F-actin content among neutrophils is determined by flow cytometric analysis of fixed, NBDphalloidin-stained neutrophils.^{13,14} The techniques utilized are readily applicable to studying neonates because they require relatively small volumes of blood. The results show that (1) basal F-actin content of neonatal neutrophils is greater than that of adult neutrophils, (2) the rate of fMLP-induced actin polymerization and maximal extent of actin polymerization in neonatal and adult cells is similar, and (3) with respect to basal F-actin content, neonatal neutrophils are composed of two subpopulations of cells. The results suggest that abnormalities of microfilamentous cytoskeleton in combination with abnormality of microtubular cytoskeleton may underlie the defective motility of neonatal neutrophils.

The basal F-actin content of neonatal neutrophils is significantly greater than that of adult neutrophils. The elevation in basal F-actin content is observed in both cord neutrophils and neutrophils obtained by venipuncture of neonates aged 1 to 8 days. No obvious correlation with mode of delivery, caesarean v vaginal, was noted, and results were reproducible during six months of studies. The differences in basal F-actin content of neonatal and adult neutrophils do not reflect a difference in the ability of their actin to polymerize because the fMLP-induced rates of actin polymerization are similar. Finally, differences in basal F-actin content cannot be explained by different amounts of polymerizable actin in neonatal and adult cells because the maximum extent of actin polymerization is similar for cells from both sources.

The major cytoskeletal consequence of the elevated basal F-actin in neonatal cells is that the magnitude of the chemotactic peptide-induced increase in F-actin content of neonatal cells (1.28-fold $\pm$ 0.24-fold) is significantly less than for adult neutrophils (2.76-fold $\pm$ 0.67-fold). The major consequence of an elevated basal F-actin to motility is less clear. Although F-actin content in fMLP-activated neutrophils correlates with the rate of cellular locomotion under some conditions,¹³ direct correlation of alterations in F-actin content of neonatal cells with the reported defects in locomotion is, at present, impossible. Two points, however, are worthy of note. First, the decreased deformability of neonatal neutrophils that is implied by motility studies in Boyden chambers of varied pore size⁶ and documented by elastimetry⁸ may relate to the increased basal F-actin content of neonatal neutrophils. Logically, the increased amounts of rigid F-actin polymers would produce increased viscosity of cytosol just as F-actin increases the viscosity of aqueous solutions. Secondly, the most consistent, reproducible defects in the motility of neonatal neutrophils—defects in chemotaxis and chemokinesis—are only apparent after

Fig 5. Comparison of fMLP-activated F-actin content among adult and neonatal neutrophils: cumulative, normalized data. Histograms from ten adults (○---○), 14 neonatal cord (▲—▲), and 15 neonatal venipuncture (●—●) samples exposed to 0.5 μ mol/L fMLP for 60 seconds are shown and normalized as described in "Materials and Methods." Shown are mean percentage of $\pm$ 1 SD of neutrophils with F-actin content at 0.5-cm intervals along the log-F-actin histogram. No values are statistically significantly different.

the cell is exposed to chemotactic factors like fMLP. Since elevated basal F-actin limits the magnitude of fMLP-induced change in F-actin content, it is logical that the decreased range of cytoskeletal responsiveness to fMLP may translate into decreased chemotaxis and chemokinesis. Obviously proof of these hypotheses awaits detailed correlation of F-actin content and distribution with chemokinesis and chemotaxis of cells.

The elevated basal F-actin content of neonatal neutrophils should not be misinterpreted as indicating that the actin in neonatal neutrophils differs in polymerizability from the actin of adult neutrophils. Historically the structure and physicochemical behavior of actin is highly conserved in species as disparate as unicellular amoeba and man, despite the occurrence of isotypic variants.¹² Experimentally, as shown here, the gross kinetics of fMLP-induced actin polymerization in adult and neonatal cells is similar. A more tenable explanation for the elevated basal F-actin content of neonatal neutrophils is to assume that in our studies F-actin content simply reflects the state of neutrophil activation and that neonatal neutrophils are more sensitive to activation by undefined factors that are either released during our assays or present during parturition and for one to eight days postnatally. Some experimental data on oxidative metabolism of neutrophils suggest such may be the case.²⁰ Document-

tation of this point will require further studies on F-actin content and oxidative metabolism of neonatal neutrophils.

Finally, our studies define subpopulations of neonatal neutrophils with respect to basal F-actin content. Subpopulations of adult neutrophils, with respect to histochemical, receptor, and antigenic characteristics have been defined.²¹ In fact, even among adult cells Wallace et al identified fMLP-activated neutrophils that differ in F-actin content and postulated that they are "slower to respond" with fMLP-induced actin polymerization.¹⁷ Our data show that the subpopulations of neonatal neutrophils clearly are not a result of differences in the polymerizability of actin because following fMLP-stimulation, one homogeneous, normally distributed group of cells is observed. As suggested by Wallace et al¹⁷ and discussed above, the differences in basal F-actin content in subgroups of neonatal cells likely reflects a difference in the sensitivity of the cell to activation, and F-actin content simply is a reflection of that activation. The presence of such subpopulations of neonatal neutrophils with respect to cytoskeletal organization invites further investigations of their importance to host defense.

CONCISE REPORT

The Synthetic RGDS Peptide Inhibits the Binding of Fibrinogen Lacking Intact α Chain Carboxyterminal Sequences to Human Blood Platelets

By Ellinor I.B. Peerschke and Dennis K. Galanakis

The α chain 572-574 Arg-Gly-Asp sequence of fibrinogen appears to play only a minor role in platelet aggregation based on the ability of fibrinogen preparations lacking α chain carboxyterminal segments to support platelet aggregation, but synthetic Arg-Gly-Asp-Ser (RGDS) peptides are capable of inhibiting platelet aggregation and fibrinogen binding. The present study thus examined the ability of RGDS peptides to inhibit platelet interactions with a plasmonic degradation product of fibrinogen (8D-50) that resembles an intermediate fragment X. Gel-filtered, human blood platelets suspended in 0.01 mol/L HEPES-buffered modified

Tyrodé's solution, pH 7.5, were stimulated with 20 μ mol/L adenosine diphosphate and the binding of ^{125} I-labeled 8D-50 or intact fibrinogen (0.01 to 0.6 mg/mL) assessed in the presence of 0 to 117 μ mol/L RGDS. The data revealed that RGDS decreased the apparent affinity of 8D-50 and intact fibrinogen for platelets but did not affect the maximum number of binding sites. RGDS thus appears to be a competitive inhibitor not only of intact fibrinogen ($K_i = 12 \pm 2 \mu$ mol/L) but also of 8D-50 ($K_i = 15 \pm 3 \mu$ mol/L) (mean $\pm$ SD, $n = 3$).

FIBRINOGEN α chains possess a carboxyterminal amino acid Arg-Gly-Asp (RGD) sequence that is also present on other adhesive glycoproteins including von Willebrand factor (vWF) and fibronectin, all of which appear to bind to the same platelet receptor, the glycoprotein IIb/IIIa complex.^{1,2} Moreover, the synthetic RGDS peptide has been shown to inhibit fibrinogen binding to platelets and platelet aggregation.³ Early studies suggested that the carboxyterminal region of the fibrinogen α chain and/or a segment containing the aminoterminal of the B β chain were involved in platelet fibrinogen interactions since derivatives lacking such segments supported platelet aggregation less well than did more intact fibrinogen.⁴ In apparent contradiction are observations of platelet aggregation supported by fibrinogen preparations with increasing carboxyterminal α chain degradation resulting in α chains of molecular weights ranging from 68,000 to 22,600 as determined by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis.⁵ These studies suggested that platelet-fibrinogen interactions were not significantly altered by the loss of carboxyterminal α chain sequences.⁵ Thus, to further characterize the RGDS-induced inhibition of fibrinogen binding, the present study compared the effect of increasing concentrations of RGDS on platelet-fibrinogen interactions in the presence of either intact fibrinogen or an early plasmonic degradation product (8D-50) that lacks the α chain 572-574 carboxyterminal RGD sequence.

MATERIALS AND METHODS

Platelet preparation. Blood was collected from healthy volunteers after obtaining informed consent according to the guidelines of the Declaration of Helsinki. It was anticoagulated with a 0.1 vol of 3.2% sodium citrate. Gel-filtered platelets (GFP) were prepared essentially as described.⁶ They were suspended in 0.01 mol/L hydroxyethyl piperazine-ethane sulfonic acid (HEPES)-buffered modified Tyrodé's solution, pH 7.5.

Fibrinogen preparation and purification. Intact, band I fibrinogen was isolated from fresh-frozen plasma as described.⁵ An intermediate plasmonic degradation product designated 8D-50 was prepared as described⁷ from a 50% clottable plasmonic fibrinogen digest. Both fibrinogens were reduced with 2% β -mercaptoethanol and electrophoresed on 7.0% SDS-polyacrylamide gels.⁸ This disclosed the virtual absence of intact α chains in 8D-50 and a major α chain remnant termed $\alpha/11$. This remnant was previously described to represent the aminoterminal third of the A- α chain and the major and longest molecular weight [MW], 25,000) A- α chain fragment in such preparations.⁹ In addition, a major portion of the β chains had been degraded displaying the $\beta/8$ fragment (MW, 54,700).⁹ Factor XIIIa cross-linked samples also displayed a band slightly cathodal to that of the γ chain corresponding to $\beta/3$ (MW, 51,100). The γ chains of 8D-50 remained intact as assessed by analysis of factor XIIIa cross-linked samples and by the presence of only trace amounts of more anodal non- α chain bands. High-performance liquid chromatography analysis¹⁰ revealed that the A peptide content of 8D-50 was identical to that of intact fibrinogen (2 residues/mol) and its B peptide content was 27% of that of intact fibrinogen, which is consistent with the presence of β chain fragments (see the preceding discussion). Both intact fibrinogen and 8D-50 were iodinated with iodine 125 using chloramine T.⁶

Fibrinogen binding. Fibrinogen binding studies were performed at room temperature using GFP stimulated with 20 μ mol/L adenosine diphosphate (ADP) in the presence of increasing concentrations of 8D-50 or intact fibrinogen and 0 to 117 μ mol/L RGDS. Specific binding was quantified as previously described.⁶ The data were analyzed by double reciprocal plots.¹¹

Platelet aggregation. GFP were aggregated with 20 μ mol/L ADP in the presence of increasing concentrations of intact fibrinogen and 8D-50 (0.01 to 0.20 mg/mL).⁶ Aggregation studies were performed at 37 °C in a dual-channel aggregometer (Chronolog Corp, Havertown, PA) with baselines set at 10% light transmission using GFP and 90% light transmission using a buffer blank.

RESULTS

Figure 1 shows the SDS-polyacrylamide gel electrophoresis profiles of reduced intact fibrinogen and 8D-50. Signifi-

Fig 1. SDS polyacrylamide cylindrical gels (7.0%) depicting the migration of intact fibrinogen (1) and 8D-50 (2) following reduction with 2% mercaptoethanol.

cant α chain degradation is present in the latter with the appearance of a predominant 25,000-MW α chain remnant. Despite this α chain degradation, the ability of 8D-50 to support ADP-induced platelet aggregation was only minimally reduced (Table 1).

The synthetic RGDS peptide inhibited the interaction between ADP-treated platelets and both ^{125} I-labeled intact fibrinogen and 8D-50 with a concentration resulting in 50% inhibition (IC_{50}) of 12.5 μ mol/L (Fig 2). To investigate further the mechanism of this inhibition, the effect of increasing doses (0 to 72 μ mol/L) of RGDS on fibrinogen and 8D-50 binding at various concentrations was quantified. Analysis of the data by double reciprocal plots of (free fibrinogen or 8D-50) $^{-1}$ v (bound fibrinogen of 8D-50) $^{-1}$ indicate that RGDS decreased the apparent affinity of both intact fibrinogen (Fig 3) and 8D-50 (Fig 4) for platelets (X intercept) but did not affect the maximum number of fibrinogen binding sites (Y intercept). Thus, RGDS appears to be a competitive inhibitor of both fibrinogen and 8D-50, even though the latter lacks the α chain carboxyterminal 572-574 RGD sequence. Inhibitor constants calculated from the binding data showed no significant difference between the ability of RGDS to compete with intact fibrinogen (K_i =

12 $\pm$ 2 μ mol/L) and 8D-50 (K_i = 15 $\pm$ 3 μ mol/L) (mean $\pm$ SD, n = 3), P > .2.

DISCUSSION

The role of fibrinogen α chains in platelet aggregation is controversial. Although the loss of α chain carboxyterminal amino acid sequences has only minor effects on platelet aggregation,⁵ the RGDS tetrapeptide that resembles the carboxyterminal amino acid sequence in position 572-575 of fibrinogen α chains was recently shown to inhibit platelet aggregation and fibrinogen binding.³ Data from the present study suggest that RGDS competitively inhibits the interac-

tion between platelets and a fibrinogen preparation (8D-50) that is missing the 572-574 α chain RGD sequence. The inhibitor constant calculated for this interaction was not statistically different from that calculated for RGDS-induced inhibition of intact fibrinogen binding to stimulated platelets.

Although early studies suggested that the carboxyterminal region of the fibrinogen α chain was involved in platelet-fibrinogen interactions, which was based on observations that derivatives lacking such segments supported platelet aggregation as well as more intact fibrinogen,⁴ the extent to which the aggregating activity of fibrinogen was compromised remained controversial.¹² Present data, showing similar platelet aggregation support by 8D-50 and intact fibrinogen and RGDS-induced inhibition of 8D-50 binding, suggest that the 572-574 α chain RGD sequence may play only a minor role in platelet aggregation.

The ability of RGDS to inhibit the binding of fibrinogen lacking intact α chain carboxytermini to ADP-treated platelets indicates that RGDS either blocks fibrinogen interactions with platelets via the α chain RGD sequence at positions 95-97 or via γ chain carboxyterminal regions. In the latter case, the competition between 8D-50 and RGDS for platelet receptors and the recent observation that fibrinogen α and γ chain binding domains may interact with different

regions on the platelet GPIIb/IIIa complex¹³ suggest that these α and γ chain binding regions may be in close proximity. This conclusion is further supported by data indicating that synthetic γ chain peptides inhibit vWF binding to stimulated platelets,¹⁴ although vWF does not possess a γ chain-like amino acid sequence.

Blast Cell Colony Assay for Umbilical Cord Blood and Adult Bone Marrow Progenitors

By Anne G. Leary and Makio Ogawa

We previously described candidate human blast cell colonies in culture of umbilical cord blood cells. However, their replating efficiencies were low, and we were unable to grow colonies from adult marrow cells. We report here a consistent method of growth and identification of human blast cell colonies that are supported by low serum culture and by delayed addition of medium conditioned by a T lymphoblast cell line, C5MJ. Nonadherent mononuclear cord blood and bone marrow cells were prepared by use of Ficoll-Paque and overnight adherence to plastic. Bone marrow cells were further enriched for progenitors by panning with monoclonal anti-My-10 antibody. Cells were plated in methylcellulose culture containing 2% fetal calf serum and supplemented with bovine serum albumin, lecithin, cholesterol, and transferrin. On day 14 of culture,

concentrated C5MJ-conditioned medium was carefully added to each dish. Blast cell colonies consisting of 18 to 100 cells were detected on days 21 to 28. Forty percent to 75% of the blast cell colonies in individual samples yielded secondary colonies upon replating (positive colonies). The replating efficiency of the positive colonies ranged from 3% to 100%. The largest secondary colony contained 7,800 cells. In addition to single-lineage colonies, multilineage colonies revealing two to five lineage combinations were seen. These results suggest that human primitive progenitors are dormant in cell cycle and that they survive in the absence of colony-stimulating factors. Human blast cell colonies may provide a unique population of progenitors for studies of the early process of human hemopoiesis.

© 1987 by Grune & Stratton, Inc.

AMURINE BLAST CELL COLONY assay has proved to be a useful tool for studies of the differentiation and proliferation of primitive hemopoietic progenitors in culture. For example, micromanipulation of individual cells from blast cell colonies provided evidence supporting the stochastic model of commitment of multipotent progenitors to monopotent progenitors.^{1,2} Serial observation of the proliferation of blast cell colonies in culture suggested that primitive stem cells are in G₀ and begin active proliferation randomly.³ Blast cell colonies also provided purified hemopoietic progenitors that were useful for defining the direct actions of colony-stimulating factors (CSF).^{4,5}

Earlier we described candidate human blast cell colonies in culture of umbilical cord blood mononuclear cells in the presence of medium conditioned by phytohemagglutinin-stimulated peripheral blood leukocytes.⁶ However, their incidence and replating efficiencies were low, which limited their usefulness. Furthermore, we were unable to find this type of colony in culture of adult human bone marrow cells. More recently, we observed that murine hemopoietic stem cells that are dormant in cell cycle survive in the absence of interleukin-3 (IL-3) and that they may be preferentially grown in culture in the presence of low concentrations of IL-3.⁷ We have applied this knowledge toward the development of a human blast cell colony assay.

In this paper, we report a consistent method of growth and identification of human blast cell colonies with high replating efficiencies that are supported by low serum culture and by delayed addition of medium conditioned by a human T lymphoblast cell line, C5MJ.

MATERIALS AND METHODS

Cell preparation. Umbilical cord blood and bone marrow samples aspirated from healthy adult volunteers were placed in 16-mL Falcon tissue culture tubes containing 400 units of preservative-free heparin (Invenex Laboratories, Inc, Melrose Park, IL). The donors were advised of the risks of marrow aspiration and gave informed consent. These studies were approved by the Institutional Review Board for Human Research. Mononuclear cells were isolated by the use of Ficoll-Paque (Pharmacia Fine Chemicals, Piscataway, NJ)

and the nonadherent fraction separated by overnight adherence to plastic. A portion of the samples was further enriched for colony-forming cells by positive indirect immune adherence using the commercial preparation of anti-My-10 monoclonal antibody,⁸ human progenitor cell antibody (Becton Dickinson, Mountain View, CA), and the "panning" technique of Engleman et al.⁹ Details of this procedure have been previously reported.⁸

Primary culture. Nonadherent mononuclear (NAMN) cells and panned My-10+ cells were cultured in 35-mm Lux suspension culture dishes (Miles Laboratories, Inc, Naperville, IL) by a modification of the technique of Iscove et al.¹⁰ One milliliter of culture consisted of 1×10^5 NAMN cord blood cells or 2×10^5 NAMN bone marrow cells or 2×10^4 My-10+ cord blood or bone marrow cells and α -medium (Flow Laboratories, Inc, Rockville, MD) with 25 mmol/L HEPES buffer (Flow), 1.2% of 1,500-centipoise methylcellulose (Fisher Scientific Co, Norcross, GA), 2% fetal calf serum (FCS) (Flow), 1% crystallized and deionized bovine serum albumin (BSA) (Sigma Chemical Co, St Louis), 5×10^{-5} mol/L mercaptoethanol, 300 μ g/mL fully iron-saturated human transferrin (98% pure, Sigma), 160 μ g/mL soybean lecithin (Sigma), 96 μ g/mL cholesterol (Sigma), and 10^{-7} mol/L sodium selenite (Sigma). Dishes were incubated at 37 °C in a humidified atmosphere of 5% CO₂ in air. On day 14 of clonal culture, 100 μ L of concentrated C5MJ-conditioned media (CM) containing 25 mmol/L HEPES buffer was carefully layered over 1 mL of culture.

CM. Media were conditioned by cells of the T lymphoblastoid cell line C5MJ that had been provided by Dr Jun Minowada,

Fig 1. A typical blast cell colony consisting of refractile, round cells that occasionally reveal taillike structures.

Roswell Park Memorial Institute, Buffalo, NY. The cells were originally obtained from patient M.J. with a diagnosis of mycosis fungoides. The human T cell leukemia virus type I-positive cells are the product of the fifth serial passage with cord blood cells. Cells were grown in α -medium containing 5% FCS and the media harvested from roller bottle culture after 1 week. Concentrated media ($30\times$) were obtained by filtration through a 1,000,000-molecular weight membrane followed by concentration through a 10,000-molecular weight membrane using a Pellicon Cassette system. Ten percent of a 1:10 or 1:20 dilution of $30\times$ media was added to each culture.

Replating experiments. On days 21 to 28 of incubation, blast cell colonies were individually lifted from the culture and suspended in 100 μ L of α -medium. The samples were gently pipetted and then added to 0.9 mL of methylcellulose medium containing 30% FCS or a mixture of 15% FCS and 15% fresh human plasma,^{11,12} 2 units of partially purified human urinary erythropoietin (Ep) with a specific activity of 370 U/mg protein (kindly provided by Dr Makoto Kawakita, Kumamoto, Japan), 15% to 30% final concentration of C5MJ CM and 1% fraction V BSA (Sigma). Cultures were incubated at 37 °C and 5% CO₂ in air. When the colonies appeared to have matured (generally after 12 to 16 days of culture), the number of cells of small colonies consisting of <500 cells was estimated in situ, and the entire colony was lifted by use of an Eppendorf micropipette, and smears were prepared using a cytospin

(Shandon Southern Instruments, Sewickley, PA). Larger colonies of >500 cells were picked, made into single-cell suspension, and aliquoted into two half samples. Half of the sample was used for counting in a counting chamber and the other half prepared for cytological examination. Slides were stained with May-Grünwald-Giemsa (Gallard Schlesinger Chemical Manufacturing Corp, Carle Place, NY),¹³ for differential counting.

RESULTS

Colony formation. Blast cell colonies consisting of 18 to 100 cells were detected between days 21 and 28 after cell plating. A picture of a representative blast cell colony is shown in Fig 1. Typically, these colonies are diffuse and consist of refractile, round cells often revealing taillike structures. These cells are also pleomorphic and continue to change their morphology during observation under an inverted microscope. When NAMN cord blood cells were plated in culture, there were macrophage clusters and colonies in addition to the blast cell colonies. However, in cultures of NAMN marrow cells there was macrophage overgrowth that hindered the identification of blast cell colonies. When My-10+ bone marrow cells were cultured, only scattered individual macrophages constituted the background, and this allowed for easy identification of blast cell colonies. Some of the apparent blast cell colonies contained nonrefractile cells that were larger than the typical blasts. These types of colonies eventually developed into macrophage colonies or revealed only a few macrophage clusters upon replating. When these colonies were excluded and only the typical blast cell colonies were replated in cultures containing C5MJ CM and Ep, a varying but high secondary colony formation was observed. A summary of the replating of the individual blast cell colonies from three cord blood samples and three My-10+ bone marrow samples is presented in Table 1. The frequencies of the blast cell colonies that yielded secondary colonies (positive colonies) and their replating efficiencies were variable but high. These features are similar to those of murine blast cell colonies we reported previously.¹⁴ The secondary colonies varied in size, with a maximum of approximately 7,800 cells per colony. The analysis of the types of secondary colonies seen in the replating of blast cell colonies derived from cultures of cord blood (sample 3 of Table 1) and bone marrow (sample 6 of Table 1) is presented in Table 2. In addition to single-lineage neutrophil, macrophage, eosinophil, basophil, and erythro-

cyte colonies, multilineage colonies of two- to five-lineage combinations were seen.

DISCUSSION

We previously reported that culture of marrow cells from normal mice in the presence of low FCS combined with the delayed addition of IL-3 favors blast cell colony formation.⁷

In the current report, we describe a similar cell culture technique that favors human blast cell colony formation from umbilical cord blood and adult bone marrow cells. Since human IL-3 was not yet available, we chose to use CM prepared from the human lymphoblast cell line C5MJ. Our observation that the addition of CM to low serum cultures 2 weeks after cell plating supported blast cell colony formation suggests that human multipotent progenitors are also dormant in cell cycle and do not require CSFs until they begin active cell proliferation. Our data also suggest that the more mature progenitors that are in active cell cycle appear to require the presence of CSFs for their continued proliferation and survival. According to a rough estimate, there was one blast cell colony-forming cell per 5×10^4 NAMN cord blood cells. There were approximately one to two blast cell colony-forming units per 1×10^4 My-10+ adult bone marrow cells. Since panning with anti-My-10 antibodies usually yields 1% of the original NAMN cells, the incidence of blast cell colony-forming cells in adult bone marrow cells was estimated to be one to two per 10^6 NAMN bone marrow cells. Blast cell colonies were detected only in cultures of My-10+ populations of adult human bone marrow cells but not NAMN marrow cells. This is a technical problem created by a high background macrophage colony growth from impure cell populations.

Although the cells that form blast cell colonies are likely to be in G_0 and begin active proliferation randomly, their exact relationship with human pluripotent stem cells has not been clarified. A consistent human blast cell colony assay is likely to contribute to our better understanding of the properties of human hemopoietic stem cells. Recently, many human CSFs have been purified and/or molecularly cloned. Furthermore, complex interactions among various types of growth factors including CSFs are being uncovered. Human blast cells will offer a unique purified population of hemopoietic progenitors for defining the direct roles of human CSFs. In addition, a consistent assay for the most primitive human progenitors to be identified in culture may be useful for elucidation of the pathophysiological mechanisms of certain hemopoietic disorders.

Cell Surface Phenotyping of Megakaryoblasts

By Tadashi Koike, Sadao Aoki, Souichi Maruyama, Miwako Narita, Toshie Ishizuka, Hirofumi Imanaka, Toyohiko Adachi, Hiroo Maeda, and Akira Shibata

Surface phenotypic characterization of megakaryoblasts, identified by platelet peroxidase activity, was investigated in four patients who showed increased proliferation of megakaryoblasts: one patient with typical features of acute leukemia, one presenting with acute myelofibrosis, and two with Down's syndrome in whom blasts disappeared spontaneously (transient abnormal myelopoiesis, TAM). MY10 and/or MY9 antigens were expressed on the surface of some megakaryoblasts, but MY7, and MY4, antigens specific to granulocytic or monocytic cells, were

not. Some megakaryoblasts were positive for only anti-HLA-DR antibodies. It was speculated that, during the differentiation of the megakaryocytic lineage, MY9 antigen appears transiently on the surface of megakaryoblasts that have lost HLA-DR antigens and have gained the glycoprotein IIb/IIIa antigen. This study also demonstrated that the proliferating blasts in some patients with TAM were mainly megakaryoblasts and suggested that the target cells in TAM are CFU-GEMM.

© 1987 by Grune & Stratton, Inc.

THE USE OF SPECIFIC monoclonal antibodies has provided important insights into leukocyte differentiation and cellular origin in leukemia.¹ These antibodies were found to be very useful in investigating the stages of differentiation in leukemic blasts. However, little is known about the cell surface phenotypes of megakaryoblasts because of the rarity of megakaryoblastic leukemia.

Platelet peroxidase (PPO), a specific enzymatic marker of megakaryocytic cell lineage, is detected in early megakaryocytes and appears earlier than platelet-specific glycoproteins (GP), such as the GP IIb/IIIa complex or GP Ib, or storage proteins in platelets, such as von Willebrand factor antigens.²⁻⁵ In this study, cell surface phenotypes were examined in patients with megakaryoblastic leukemia in whom the proportions of blast cells were more than 45% and PPO activity was detected in more than 65% of the blasts.

MATERIALS AND METHODS

Patients. Clinical data on all patients are shown in Table 1. Patient 1 was an infant without Down's syndrome. Aspiration of bone marrow was easy, and the presence of myelofibrosis was unlikely. Patient 2 presented with acute myelofibrosis. Circulating blasts increased gradually. Patients 3 and 4 had Down's syndrome with a spontaneous disappearance of proliferating blasts. Regarding the aspiration and biopsy of bone marrow, all patients were advised of procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent.

Blood smears and cytochemical studies. Blood smears were stained with May-Grünwald-Giemsa. Cytochemical reactions for myeloperoxidase (MPO), Sudan black B, α -naphthyl acetate esterase, α -naphthyl butyrate esterase, acid phosphatase, and periodic acid-Schiff (PAS) were performed by conventional methods.⁶

Electron microscopic studies. PPO was detected by the method of Anderson et al⁷ or Breton-Gorius et al² with a slight modification as described elsewhere.⁵ More than 200 blasts were examined, and the blasts positive only in perinuclear space or endoplasmic reticulum were regarded as PPO-positive. Positive blasts in granules or Golgi cisternae were regarded as MPO-positive.

Cell surface phenotyping. For the detection of surface antigens, samples were analyzed using a Spectrum III (Ortho Diagnostics, Westwood MA). A population of blast cells was clearly distinguished from the lymphocytes, monocytes, and granulocytes on the basis of light-scattering properties. Monoclonal antibodies used in this study were as follows: OKT3 (CD3), OKT11 (CD2), OKT4 (CD4), and OKT8 (CD8) purchased from Ortho Pharmaceutical Corp, Raritan, NJ; J5 (CD10), B4 (CD19), B1 (CD20), MY7

(CDw13), MY4 (CDw14), MY9, and MY10 purchased from Coulter Immunology, Hialeah, FL; HLA-DR and LeuM3 purchased from Becton Dickinson, Mountain View, CA; and TP80 (IgG1), which detects GP IIb/IIIa antigen,^{8,9} and another monoclonal anti-GPIIb/IIIa antibody, PLT-2, purchased from Cappel Laboratories, Cochranville, PA. The positivity for the monoclonal anti-GPIIb/IIIa antibodies was also examined by an indirect immunalkaline phosphatase technique⁵ or by the alkaline phosphatase anti-alkaline phosphatase (APAAP) method.¹⁰ Fc binding of these antibodies to the stained cells was excluded by the absence of reactivity with monoclonal antibodies directed to unrelated antigens of the same immunoglobulin subclasses and by the findings that the saturation of Fc receptors by preincubation with normal rabbit serum had no effect on the APAAP staining results obtained using monoclonal antibodies to GP IIb/IIIa. The results of indirect immunalkaline phosphatase staining conjugated F(ab')₂ immunoglobulin were almost the same as those of APAAP staining. Terminal deoxynucleotidyl transferase (TdT) activity was detected by immunofluorescence using a Bethesda kit (Bethesda Research Laboratories Rockville, MD).

RESULTS

Light microscopic cytochemistry. Almost all of the patients' blasts were negative for peroxidase, Sudan black B, and α -naphthyl butyrate staining but were positive for acid phosphatase. Blasts in patient 1 stained strongly for α -naphthyl acetate, whereas blasts in the other patients stained weakly for this enzyme. Some blasts from all patients were positive for PAS.

Percentages of cells positive for ultrastructural cytochemistry and immune markers refer to the percentage of blasts as assessed by their characteristic morphology and by size gating (see Materials and Methods).

Abbreviations: BM, bone marrow; PO(-), blasts negative for peroxidase activity; TP80 and PLT-2, antiplatelet GP IIb/IIIa antibodies; NT, not tested.

Electron microscopic cytochemistry. In all patients more than 65% of the blasts were positive for PPO in perinuclear space and endoplasmic reticulum (Table 1, Fig 1). Less than 5% of the blasts were positive for peroxidase in granules and Golgi apparatus.

Cell surface phenotyping. The immunologic markers of the blasts are shown in Table 1. Most of the blasts from patient 1 reacted to TP80 (Fig 2), whereas most of the blasts from patient 2 were negative for this antibody. The proportions of cells positive for TP80 were similar to those of PPO-positive cells in patients 1 and 3, whereas in patients 2 and 4, the proportions of TP80-positive cells were rather low compared with those of PPO-positive blasts. In all patients, the blasts were negative for lymphoid markers such as B2, B4, OKT3, OKT11, OKT4, OKT8, J5, and TdT. In contrast, a considerable proportion of the blasts were positive for

MY10 and MY9 in patients 1, 3, and 4, but their blasts were rarely positive for MY7 and MY4. In patient 2, the blasts were negative for MY9 and TP80 but positive for HLA-DR, whereas in patient 1, they were positive for both MY9 and TP80 but negative for HLA-DR.

DISCUSSION

We encountered four patients in whom the proliferating blasts were recognized as megakaryoblasts, although the patients' clinical features varied. For identification of megakaryoblasts, detection of PPO activity is necessary when the proportion of blasts positive for antiplatelet antibodies is small because PPO activity appears earlier than platelet-specific glycoproteins such as GP IIb/IIIa antigens during the process of megakaryocyte maturation.³⁻⁵ In this study, we examined whether other markers, especially myeloid markers, are expressed on megakaryoblasts with PPO activity. A considerable proportion of blasts was positive for MY10 and/or MY9 in patients 1, 3, and 4, whose blasts were rarely positive for MY7 or MY4. It is noteworthy that most of the blasts in patient 1 were positive for MY10 and MY9 in addition to high proportions of cells positive for anti-GPIIb/IIIa and PPO activity. MY10 antigen is a cell surface protein with an apparent molecular weight of 115 kilodaltons and was produced after immunization with KG-1a human leukemia cells.¹¹ Cell sorting and panning experiments demonstrated that CFU-GM and BFU-E were MY10-positive. The MY9 monoclonal antibody was produced by Griffin et al¹² following immunization with the cells of a patient in the blast crisis of chronic granulocytic leukemia. MY9 antigen is expressed on CFU-GM, myeloblasts, promyelocytes, myelocytes, and monocytes. Approximately 50% of BFU-E and some of CFU-GEMM are also MY9-positive, although more mature erythrocytic cells are negative for this antigen.^{12,13} The present results suggest that megakaryoblasts, which are megakaryocyte precursors, express MY10 and MY9, although mature megakaryocytes and platelets are negative for these antibodies. The blasts of our patients were rarely positive for MY7 and MY4, which are markers of more myeloid development. MY7 antigen is specific to granulocytic and monocytic cells.¹⁴ MY4 antigen is expressed

Fig 1. Electron micrographs of megakaryoblasts from the blood of patients 2 (left) and 4 (right). Reaction products for platelet peroxidase are present in the nuclear envelope and endoplasmic reticulum in megakaryoblasts. Unstained sections; original magnifications $\times 6000$ (A) and $\times 5000$ (B).

Fig 2. A marrow smear from patient 1 showing replacement of marrow by leukemic blasts (May-Grünwald-Giemsa stain). Most of the blasts have prominent cytoplasmic blebs. (B) A marrow smear from patient 1 showing positive reddish granular staining of GPIIb/IIIa antigen on the surface of all the blasts (APAAP stain using TP80 and fast red TR salt as the color reagent). (C) A blood smear from patient 3 showing reaction for TP80 (APAAP stain). Most of the blasts are strongly positive. (D) Blasts from patient 3 (May-Grünwald-Giemsa stain). Two blasts have a smooth margin without blebs, and one has protrusions.

strongly on monocytic cells and weakly on granulocytic cells.¹⁴

There was heterogeneity of surface marker expression (GPIIb/IIIa, MY10/MY9, and HLA-DR) among patients. This heterogeneity may be related to the level of maturation. Figure 3 illustrates the possible order of appearance of markers in the maturation of the megakaryocytic cell lineage based on the present data. PPO activity was detected in immature megakaryoblasts that retain HLA-DR antigens and do not express MY9 antigen. MY9 antigen may appear on megakaryoblasts that have lost HLA-DR antigens and have expressed GPIIb/IIIa antigens.

The proposed model is based on the data from leukemic megakaryocytic precursors. Therefore, the relationship between the level of megakaryocytic maturation and surface

GPIIb/IIIa	=====	
PPO		=====

Fig 3. The possible order of appearance of markers in the maturation of megakaryoblasts.

marker expression should be confirmed in megakaryocyte colony-forming assays using normal bone marrow cells treated with monoclonal antibodies and complements.

A self-limited blastic proliferation, indistinguishable from acute leukemia except for its disappearance without therapy, has been noted in infants with Down's syndrome.¹⁵ This phenomenon is designated as transient abnormal myelopoiesis (TAM).¹⁶ In addition to previous reports that proliferating blasts in TAM were usually myeloblasts, the results found in patients 3 and 4, ie, mainly the megakaryocytic nature of proliferating blasts, suggest that the target cells in TAM are CFU-GEMM.

CONCISE REPORT

Molecular Analysis of Interferon-Induced Suppression of Philadelphia Chromosome in Patients With Chronic Myeloid Leukemia

By G. Yoffe, M. Blick, H. Kantarjian, G. Spitzer, J. Gutterman, and M. Talpaz

Treatment with recombinant human interferon alpha-A (Roferon-A) is associated with stable suppression of the population of cells that display the Philadelphia (Ph¹) chromosome in some patients with chronic myelogenous leukemia (CML) as defined by cytogenetic analysis. Southern blot analyses employing a 3' breakpoint cluster region (*bcr*) probe (Pr-1) were performed to confirm a complete suppression of the Ph¹⁺ chromosome-positive clone of cells at the DNA level. The complete disappearance of rearranged

restriction fragments of the *bcr* gene, which were a characteristic of the disease prior to Roferon-A therapy, was accompanied by the restoration of normal bone marrow and achievement of durable ongoing complete remission for 9 and 6 months, respectively, in two patients with Philadelphia-positive (Ph¹⁺) CML. Molecular analysis is a valuable probe for monitoring the clinical course of disease in patients with Ph¹⁺ CML.

© 1987 by Grune & Stratton, Inc.

THE ANTIPROLIFERATIVE activity of human alpha interferon has been demonstrated in a number of human tumors *in vivo*¹ as well as in normal myeloid and myeloid leukemic progenitor cells *in vitro*.^{2,3} Recombinant human interferon alpha-A (Roferon-A) has recently been shown to induce hematologic remission in most of the patients with chronic myelogenous leukemia (CML) in the early benign phase.⁴ Therapy with Roferon-A resulted in durable Philadelphia (Ph¹) chromosome suppression (cytoconversion) in some of these patients. Other studies have also demonstrated a complete, albeit transient, suppression of the Ph¹⁺ clone of cells following intensive chemotherapy.⁵

Because more than 90% of the cases of CML display the Ph¹ chromosome, which is the result of a 9:22 translocation, this constitutes a hallmark of the disease.⁶ The *c-abl* oncogene, located on chromosome 9, and the breakpoint cluster region (*bcr*) gene, located on chromosome 22, are juxtaposed in the Ph¹⁺ CML,^{7,8} thus producing a *bcr/abl* chimeric mRNA transcript^{9,10} and a chimeric fusion protein.^{11,12} Upon the introduction of molecular probes capable of identifying this alteration,^{8,13} molecular analysis along with cytogenetic analysis⁶ can be used for monitoring therapies with interferon, intensive chemotherapy, and other treatment modalities throughout the course of the disease in patients with CML.

In this study, suppression of the Ph¹ chromosome clone of cells in two patients with Ph¹⁺ CML following treatment with Roferon-A was accompanied by the loss of an aberrant restriction fragment of the *bcr* gene, which was characteristic of the disease prior to Roferon-A therapy. This provides evidence at the DNA level for suppression of the Ph¹⁺ clone of cells in two patients with CML treated with Roferon-A.

MATERIALS AND METHODS

Case Reports

Patient 1. The diagnosis of Ph¹⁺ CML was made in this 65-year-old Latin American female in September 1984. She remained untreated until December 1984 when daily intramuscular injections of 5×10^6 U/m² of Roferon-A were started. Complete hematologic remission was observed after 8 weeks of treatment, which was manifested by a decrease in the WBC count from $116 \times 10^3/\mu\text{L}$ to $3.4 \times 10^3/\mu\text{L}$ and a return of an enlarged spleen to normal size. One hundred percent of the cells in the blood and bone marrow were initially Ph¹⁺. A bone marrow cytogenetic study following 3 months of therapy demonstrated a decrease of the Ph¹⁺ cells to 30%. A repeat bone marrow study following 6 months of treatment

demonstrated complete suppression of the Ph¹⁺ clone of cells, a finding that persisted in two additional studies at 9 and 12 months following the initiation of therapy. Thus the Ph¹⁺ cells remained continuously suppressed for 9 months.

Patient 2. The diagnosis of Ph¹⁺ CML was made in this 32-year-old white female in June 1984. She was treated initially with hydroxyurea for 2 months, and in October 1984, daily intramuscular injections of 5×10^6 U/m² of Roferon-A were started. Prior to treatment with Roferon-A, the patient's peripheral WBC was $18.8 \times 10^3/\mu\text{L}$, and her platelet count was $566 \times 10^3/\mu\text{L}$. The bone marrow cellularity was 100%, and 100% of the cells were Ph¹⁺. The hematologic parameters of her disease improved gradually, and hematologic remission was achieved 7 weeks after the Roferon-A therapy was started. At that time, her WBC decreased to $3.4 \times 10^3/\mu\text{L}$, and her platelets decreased to $125 \times 10^3/\mu\text{L}$. Subsequently, after 14 weeks of therapy, the treatment dose of Roferon-A was reduced to 2.5×10^6 U/m² when the bone marrow cellularity decreased to 40% and cytogenetic analysis demonstrated a decrease of the Ph¹⁺ cells to 70%. The Ph¹⁺ clone of cells decreased further to 30% at 6 months and to 10% at 9 months of therapy. Complete suppression of the Ph¹⁺ clone of cells occurred after 12 months of therapy and has been sustained after 15 and 18 months after therapy was started.

DNA Isolation and Southern Blotting

Blood and bone marrow samples were obtained from patients after they had been fully advised of the procedure and attendant risks in

accordance with institutional guidelines and had given informed consent. High-molecular weight DNA was extracted from peripheral blood leukocytes and bone marrow cells by methods described elsewhere.¹⁴ The digested DNA was electrophoresed in a 0.8% agarose gel in a buffer containing 0.4 mol/L Tris, 20 mmol/L EDTA, and 100 mmol/L Na acetate, denatured, neutralized, and transferred to nitrocellulose filters by the Southern blot method.¹⁵ Prehybridization and hybridization were carried out as described previously.¹⁵ A *bcr* probe (Pr-1) purchased from Oncogene Sciences (Mineola, NY) and corresponding to the breakpoint cluster region on chromosome 22⁸ was labeled to a specific activity of 1 to 3×10^8 cpm/ μ g of DNA by nick translation. Following hybridization, the filters were washed under stringent conditions, air-dried, and exposed to x-ray film for one to five days at -70°C .

RESULTS

High-molecular weight DNA was obtained from the peripheral blood of both patients before treatment with Roferon-A and from the peripheral blood of a normal donor. The DNAs were digested by *Bam*HI and *Bgl*II restriction endonucleases and analyzed by Southern blot using a 3' *bcr* probe (Pr-1). Analysis of the DNA from patient 1 demonstrated abnormal 11-kb *Bam*HI and 9-kb *Bgl*II hybridizing fragments in addition to the normal 3.3-kb *Bam*HI and 5-kb *Bgl*II *bcr* fragments (Fig 1, panel 1). Similarly, patient 2 disclosed abnormal 7.6-kb *Bam*HI and 9-kb *Bgl*II hybridizing fragments in addition to the normal *bcr* restriction fragments (Fig 1, panel 2). Repeat analysis of the DNA from both patients' peripheral blood was carried out on samples obtained 12 months after Roferon-A therapy was started. This analysis disclosed that the rearranged hybridizing fragments were not detected by Southern blot using the same *bcr* probe (Fig 2, panel 2). Twelve months after Roferon-A therapy was started, bone marrow DNA was also obtained from patient 1, and a similar Southern blot analysis disclosed no *bcr* rearrangement (Fig 2, panel 1). To determine the sensitivity of our Southern blot assay, a mixing experiment was performed (Fig 3). Using DNA from a normal donor and DNA from a CML patient with an additional abnormal 3-kb *Bgl*II restriction fragment, we found that as little as 5%

Fig 1. Southern blot analysis demonstrating the normal 3.3-kb *Bam*HI (lane 3a) and 5-kb *Bgl*II (lane 3b) hybridizing fragments in DNA obtained from a normal volunteer and both the normal and rearranged hybridizing fragments in DNA obtained from the leukemic cells of patient 1 (panel 1) and patient 2 (panel 2).

Fig 2. Southern blot analysis demonstrating the normal 3.3-kb *Bam*HI (lane a) and 5.0-kb *Bgl*II (lane b) and the loss of the rearranged *bcr* fragments in the cells obtained from the bone marrow of patient 1 (panel 1) and peripheral blood of patient 2 (panel 2) after both patients had received 12 months of Roferon-A therapy.

contamination of DNA from the Ph^{1+} cells was clearly detectable as a faint band after a long exposure (120 hours). Therefore, in this assay, the level of detection was approximately 5% by Southern blot analysis.

DISCUSSION

We have demonstrated the disappearance of the Ph^{1+} clone of cells in two patients with CML following treatment with Roferon-A. In addition to cytoconversion of the Ph^1 chromosome in all analyzed metaphases, a rearranged *bcr* DNA fragment characteristic of the patients' disease prior to Roferon-A therapy completely disappeared at a time coincidental with hematologic remission.

Previous studies have demonstrated the restoration of nonclonal hematopoiesis in patients with CML following intensive chemotherapy.¹⁶ Similarly, we have reported partial and complete suppression of the Ph^{1+} clone after alpha interferon therapy.^{4,17} In this study, we confirm that the clone

Fig 3. Southern blot analysis of a mixing experiment demonstrating the sensitivity of our assay. DNA (10 μ g) from a normal volunteer was analyzed using the *Bgl*II restriction endonuclease and the *bcr* probe (lane 1). DNA (10 μ g) from a patient with CML was analyzed in a similar fashion (lane 9) and then serially diluted so that 50% of the DNA in lane 8 is from the patient with CML, 25% in lane 7, 10% in lane 6, 5% in lane 5, 2.5% in lane 4, 1% in lane 3, and 0.5% in lane 2.

of cells bearing a DNA rearrangement associated with the formation of the Ph¹ chromosome¹⁸ in CML disappeared from the patients' blood and bone marrow. We have further demonstrated that as little as 5% Ph¹⁺ cells in any given sample can be detected by using Southern blot analysis. The possibility exists that the Ph¹⁺ clone was still present in less than 5% of the bone marrow cells.

Although the Ph¹ chromosome and rearranged *bcr* gene are associated with more than 90% of the cases of CML,^{8,19} it is still unknown whether suppression of the clone bearing the rearranged gene and the Ph¹ chromosome restores the bone marrow to a normal polyclonal pattern. In this instance, a second clonal marker such as the glucose-6-phosphate dehydrogenase isoenzyme pattern²⁰ or the restriction fragment length polymorphism of the hypoxanthine-guanine phosphoribosyl-transferase gene²¹ may help determine whether the

cells that remain when patients are in remission represent the same abnormal clone and simply lack the Ph¹ chromosome and the *bcr* rearrangement. However, since the clinical and hematologic features of CML disappeared completely in these two patients, it is unlikely that the hematopoietic cells of these patients in remission still consist of a monoclonal population.

Demonstration of the suppression of the Ph¹⁺ clone by cytogenetic analysis may reflect only the events in a specific cell population that happens to enter mitosis. Molecular analysis, however, circumvents this problem and provides information on the total cell population (dividing and nondividing cells as well). Therefore, the demonstration of complete suppression of an existing gene rearrangement supports the notion that these patients with CML were in complete remission at the molecular level.

Differences in Coagulant and Fibrinolytic Activities of Cultured Human Endothelial Cells Derived From Omental Tissue Microvessels and Umbilical Veins

By Wolfgang Speiser, Elisabeth Anders, Klaus T. Preissner, Oswald Wagner, and Gert Müller-Berghaus

Large vessel and microvascular endothelial cells were compared in their capacity to synthesize and secrete coagulant and fibrinolytic factors. Human omental tissue microvascular endothelial cells (HOTMEC) and human umbilical vein endothelial cells (HUVEC) were isolated, grown to confluency under identical conditions, and studied in primary cultures. After an incubation period of 12 hours in serum-free medium, the conditioned medium of confluent HOTMEC contained 100-fold higher levels of tissue plasminogen activator (tPA) antigen than that of HUVEC. The conditioned media as well as the lysates of both cell types did not contain any free tPA activity, but the free plasminogen activator inhibitor capacity was found

intracellularly as well as extracellularly. Although von Willebrand factor was detected in both cell types by immunofluorescence, measurable amounts were only found in HUVEC using an enzyme-linked immunosorbent assay. The kinetics of protein C activation by thrombin on the surface of once-passaged cells were identical for HOTMEC and HUVEC. The present study indicates that cultivated HOTMEC produce larger quantities of tPA than HUVEC do, possess smaller amounts of von Willebrand factor than HUVEC do, and express thrombomodulin for protein C activation as effectively as HUVEC.

© 1987 by Grune & Stratton, Inc.

ENDOTHELIAL CELLS are involved in the regulation of coagulation and fibrinolysis. These cells are known to synthesize and release components of the coagulation system such as tissue factor,¹ von Willebrand factor (vWF),² and factor V³ as well as components of the fibrinolytic system such as tissue plasminogen activator (tPA) and plasminogen activator inhibitor (PAI).⁴ Quiescent, nonstimulated endothelial cells release an excess of fast-acting PAI over tPA, and therefore tPA antigen but almost no free tPA activity is found in the blood^{5,6} as well as in endothelial cell-conditioned medium.⁴

The expression of thrombomodulin on the endothelial cell surface facilitates the activation of protein C by thrombin, which binds to thrombomodulin, thereby losing its fibrin-generating potency. Activated protein C degrades activated factor V and factor VIII:C.⁷ Furthermore, activated protein C may enhance fibrinolysis by limiting PAI activity.⁸

In the present study some significant coagulant and fibrinolytic activities of human umbilical vein endothelial cells (HUVEC) were compared with those of human omental

tissue microvascular endothelial cells (HOTMEC) by using immunologic as well as functional assay systems. It was found that HOTMEC generate larger amounts of tPA and PAI than HUVEC, whereas HUVEC possess more vWF. Protein C seems to be equally well activated by thrombin on the surface of HOTMEC as on that of HUVEC.

MATERIALS AND METHODS

Cultivation of endothelial cells. HOTMEC were isolated as described previously.^{9,10} Briefly, 10 to 15 g human omental tissue was obtained from patients undergoing cholecystectomy. All patients were advised of procedures and attendant risks by the surgeon, in accordance with the institutional guidelines, and gave informed consent. The tissue was dissected into small pieces and incubated in phosphate-buffered saline (PBS) containing 2 mg/mL collagenase (GIBCO, Karlsruhe, FRG) for 15 minutes at 37 °C. After the removal of undissociated tissue fragments by a nylon screen (diameter Ø, 400 µm), capillary fragments were separated from contaminating cells by a further filtration step (nylon screen; Ø, 30 µm) and then by velocity sedimentation at unit gravity (PBS containing 5% bovine serum albumin [wt/vol]). HUVEC were isolated according to Jaffe et al.¹¹ The cells obtained by these procedures were identified as endothelial cells by their typical cobblestonelike growth pattern, by positive immunofluorescence staining for vWF and by immunoreactivity with a monoclonal antibody directed against endothelial cells.¹⁰ Both cell types were seeded on Petri dishes (35 × 10 mm; Becton Dickinson, Heidelberg, FRG) precoated with fibronectin (Behringwerke, Marburg, FRG) and grown to confluency in Waymouth's MB 752/1 culture medium supplemented with 20% (vol/vol) fetal calf serum, 100 U/mL penicillin, 100 µg/mL streptomycin, 2 mmol/L glutamine (all culture medium reagents were from GIBCO), and 100 µg/mL endothelial cell growth supplement (Sigma Chemical Co, Munich).

Incubation of endothelial cells in serum-free medium. Four to six days after seeding, two dishes with confluent monolayers of endothelial cells derived from a single umbilical cord or from omental tissue of a single donor were incubated in serum-free medium (SFM) containing 1% (wt/vol) human serum albumin (Sigma) and 2 mmol/L D(+)-glucose (Merck, Darmstadt, FRG). Aliquots of the supernatants were taken at six and 12 hours, centrifuged at 180 g, and stored at -30 °C up to 8 weeks until assessment. At the end of the 12-hour incubation, the cells were washed with SFM and detached from the dishes by incubation with

1 mL 150 mmol/L NaCl, 0.05% (wt/vol) trypsin, and 1 mmol/L EDTA for two minutes at 37 °C. Thereafter, trypsin was inhibited by adding 1 mL SFM containing 6 mg/mL soya bean trypsin inhibitor (GIBCO). For the assessment of tPA antigen, PAI capacity, and vWF antigen in the cells, an aliquot was removed for determination of the cell count, and the remaining suspension was centrifuged at 180 g for five minutes (the supernatants contained $5.2\% \pm 2.1\%$ [mean $\pm$ SD, $n = 8$] of the amount of tPA antigen (HOTMEC) and $30.1\% \pm 9.2\%$ of the amount of vWF [HUVEC] measured in cell lysates). The cells were then resuspended in 1 mL 0.1 mol/L Tris-HCl, 0.1% (wt/vol) Tween 80, 0.01% (wt/vol) sodium azide, pH 7.42, and sonicated by a cell disruptor (Branson, Soest, The Netherlands) for one minute at 4 °C. After centrifugation at 180 g for five minutes, the supernatants were stored at -30 °C up to 8 weeks until assessment.

tPA and PAI. tPA antigen was measured by an enzyme-linked immunosorbent assay (ELISA) as described earlier.⁵ Reverse fibrin autography and determination of PAI activity were performed as described elsewhere.⁶

vWF. vWF antigen was measured by an ELISA (Boehringer Mannheim, Mannheim, FRG). One unit of vWF was defined as the amount of antigen contained in 1 mL of pool plasma. Immunofluorescence was performed as described elsewhere.¹⁰

Activation of protein C on the endothelial cell surface. Confluent monolayers of pooled and once-passaged cells isolated from several umbilical cords or from omental tissue of several donors were used for the experiments, which were performed as described elsewhere.¹⁰

RESULTS

tPA and PAI. Determinations were performed on individual primary cultures of endothelial cells isolated from omental tissue (HOTMEC) of eight donors and from eight different umbilical cords (HUVEC). In the course of 12-hour incubation in SFM, tPA antigen levels increased in the endothelial cell-conditioned medium (ECCM) of HOTMEC as well as in that of HUVEC (Fig 1). tPA levels in ECCM of HOTMEC (45.1 ± 11.9 ng/ 10^6 cells; mean $\pm$ SD; $n = 8$) were about 100-fold higher than in ECCM of HUVEC (0.41 ± 0.15 ng/ 10^6 cells) at the end of the incubation period. When the total amount of tPA antigen (ECCM plus cell lysates) measured in HOTMEC (62.5 ng/ 10^6 cells) was compared with that of HUVEC (0.66 ng/ 10^6 cells), a 100-fold excess of HOTMEC over HUVEC was calculated. Free tPA activity was not detectable in ECCM and cell lysates of HOTMEC or of HUVEC, but the free PAI capacity (PAI-cap) was found to increase in the course of incubation (Fig 2). After an incubation time of 12 hours, the PAI-cap amounted to 91.5 ± 11.0 U/ 10^6 cells in the lysates and 56.1 ± 9.8 U/ 10^6 cells in ECCM of HOTMEC and to 15.9 ± 7.9 U/ 10^6 cells in the lysates and 21.4 ± 17.1 U/ 10^6 cells in ECCM of HUVEC. The molecular weights (mol wt) determined by reverse fibrin autography of PAI in ECCM of HUVEC and HOTMEC were identical and amounted to 49,000 and those of PAI in cell lysates 52,000 (Fig 3). In cell lysates, a second band with a mol wt of 31,000 was identified.

vWF. Although vWF was demonstrated in both cell types by immunofluorescence (data not shown), vWF could be measured quantitatively only in HUVEC (Fig 4). In ECCM of HUVEC, vWF amounted to $29.2 \pm 12.3 \times 10^{-3}$

Fig 1. tPA antigen levels (mean $\pm$ SD, $n = 8$) in serum-free conditioned medium of HOTMEC ($\square$) and HUVEC ($\circ$) after six and 12 hours of incubation. Intracellular levels of tPA antigen (mean $\pm$ SD, $n = 8$) of the same HOTMEC ($\blacksquare$) and HUVEC ($\bullet$) at the end of the 12-hour incubation time are given.

U/ 10^6 cells (mean $\pm$ SD; $n = 8$) after six hours and $42.8 \pm 23.4 \times 10^{-3}$ U/ 10^6 cells after 12 hours' incubation. A total of $30.4 \pm 11.7 \times 10^{-3}$ U/ 10^6 cells were measured within the cells after a 12-hour incubation.

Activation of protein C. The activation of protein C by thrombin on the cell surfaces revealed identical profiles in both cell types (Fig 5).

DISCUSSION

The concentrations and activities of relevant coagulant and fibrinolytic factors synthesized by HOTMEC and HUVEC were compared. Although the cells were grown under identical conditions, marked differences in the content and the release of these factors from the cells into the culture medium were observed.

HOTMEC contained and released markedly more tPA than HUVEC. tPA was found within the cells as well as in ECCM in both cell types in an inactive form, which suggests that tPA was completely complexed to PAI under the conditions of this study. On the other hand, it is known that

Fig 2. PAI-cap (mean $\pm$ SD, $n = 8$) of serum-free conditioned medium of HOTMEC ($\square$) and HUVEC ($\circ$) after six and 12 hours of incubation. Intracellular PAI-cap (mean $\pm$ SD, $n = 8$) of the same HOTMEC ($\blacksquare$) and HUVEC ($\bullet$) at the end of the 12-hour incubation time are given.

Fig 3. Reverse-phase fibrin autography of cell lysates and ECCM of HOTMEC and HUVEC after incubation of the cells in SFM for 12 hours. Lane 1, ECCM of HUVEC; lane 2, cell lysate of HUVEC; lane 3, ECCM of HOTMEC; lane 4, cell lysate of HOTMEC.

endothelial cells can release an excess of tPA over PAI when they are stimulated, eg, in physical exercise or venous occlusion.¹² The higher amounts of tPA found in HOTMEC may therefore be regarded as a strong potential fibrinolytic capacity.

Active PAI were detected in ECCM and lysates of both cell types by a functional assay as well as by reverse fibrin autography. The high-mol wt PAI in ECCM showed a mol wt approximately 3,000 smaller than that in cell lysates, thus confirming the observation of Kooistra et al¹³ that PAI is degraded to a lower mol wt form after secretion into ECCM. The fact that PAI activity was found also at a mol wt of 31,000 in cell lysates might be due to partial degradation of the 52,000-mol wt molecule during preparation of cell lysates followed by a shift in mol wt as described recently by Levin.¹⁴

vWF was detected in HOTMEC as well as in HUVEC. Obviously, the concentration of vWF is very low in HOT-

Fig 4. vWF levels (mean $\pm$ SD, $n = 8$) in serum-free conditioned medium of HOTMEC ($\square$) and HUVEC ($\circ$) after six and 12 hours of incubation. Intracellular levels of vWF (mean $\pm$ SD, $n = 8$) of the same HOTMEC ($\blacksquare$) and HUVEC ($\bullet$) at the end of the 12-hour incubation are given.

Fig 5. Protein C activation by thrombin on the surface of HUVEC (A) and HOTMEC (B). The cells were preincubated with 45 nmol/L purified human α -thrombin for 15 minutes at 37°C. After the removal of thrombin, 65 nmol/L purified human protein C was applied, and the activity (mean $\pm$ SD, $n = 4$) of the generated activated protein C in the supernatant was measured after different incubation times with the chromogenic substrate S-2266 (Kabi Vitrum AB, Stockholm).

MEC because it could be quantitatively determined by ELISA only in HUVEC. Limited amounts of vWF in microvascular endothelial cells may be of importance in a well-balanced system that provides enough vWF for platelet adhesion in the case of microvessel injury but prevents microthrombosis.

Protein C was activated by thrombin on the surface of both cell types to a similar degree, which suggests the existence of equal numbers of thrombomodulin receptors on the surface of HOTMEC and HUVEC. Considering the relatively large surface made available by the endothelial cells in the microvasculature in relation to the blood volume, a high anticoagulant capacity mediated by protein C activation can be assumed in the microcirculation compared with large vessels.

The present study demonstrates that endothelial cells isolated from different vascular sources provide quantitatively different fibrinolytic and anticoagulant capacities. These quantitative differences may be of importance to maintain a free and constant blood flow. The low incidence of capillary microthrombosis compared with large-vessel thrombosis may be explained by the high fibrinolytic and anticoagulant activities in the microcirculation.

T Cell γ Gene Rearrangements in Hematologic Neoplasms

By Norio Asou, Masao Matsuoka, Toshio Hattori, Fumio Kawano, Shuichiro Maeda, Kazunori Shimada, and Kiyoshi Takatsuki

Rearrangements of the T cell γ ($T\gamma$) gene were studied in primary neoplastic cells from 75 patients with leukemia or lymphoma. $T\gamma$ gene rearrangements were observed in 19 of 21 T cell neoplasms; 14 of 21 immature B cell leukemias, including 4 out of 5 patients with rearrangements of both immunoglobulin heavy-chain (JH) and T cell receptor β chain ($T\beta$) genes; none out of 14 B cell neoplasms; all 3 unclassified neoplasms; and none out of 16 nonlymphoid leukemias. Thus, $T\gamma$ gene rearrangement is frequently found in immature B cells and is not always found in T cells showing $T\beta$ gene rearrangement, but it is not detected in

nonlymphoid cells. Furthermore, $T\gamma$ gene rearrangement in cells with the germline configuration of the JH and $T\beta$ genes was observed. These results indicate that the detection of $T\gamma$ gene rearrangement does not allow a clear assignment to a particular lineage. However, an analysis of $T\gamma$ gene rearrangement provides a further potential tool to establish the lymphoid cellular origin and clonality of hematologic neoplasms and identify the normal stages of lymphocyte differentiation.

© 1987 by Grune & Stratton, Inc.

LYMPHOCYTES are known to express antigen recognition molecules, immunoglobulin (Ig) in B cells, and T cell receptors (TCR) in T cells. Genes for Ig and TCR share certain homologies including similar nucleotide segments consisting of variable (V), diversity (D), joining (J), and constant (C) regions and rearrangements to become functionally active during early B or T cell development, respectively.^{1,2} Therefore, an analysis of the Ig and TCR β chain ($T\beta$) gene rearrangements has become a useful tool for determining the lineage and clonality of lymphoid neoplasms.³⁻⁵

A third gene that rearranges in T cells, designated the T cell γ ($T\gamma$) gene, also exhibits sequence similarity with Ig gene segments and undergoes rearrangement in both suppressor/cytotoxic and helper T cells.⁶⁻⁹ However, the product of the $T\gamma$ gene has not yet been identified, and its precise function remains uncertain. One approach to understanding the function of this molecule is to characterize the diversity of the assembled and expressed $T\gamma$ gene in various cell types including neoplastic cells. In addition, it is of importance to determine whether $T\gamma$ gene rearrangements provide insight into the cellular origin and clonality of lymphoid neoplasms. To our knowledge, $T\gamma$ gene rearrangements in non-T cells have been reported only by Griesser et al¹⁰ who detected rearrangements of the $T\gamma$ gene in six out of seven B cell lymphomas. In these respects, rearrangements of Ig heavy-chain (JH), $T\beta$, and $T\gamma$ genes were studied in 35 B lineage

neoplasms, 21 T cell neoplasms, 3 unclassified neoplasms, and 16 nonlymphoid neoplasms.

MATERIALS AND METHODS

Patients and cell preparations. Twenty-one patients with immature B cell acute lymphoblastic leukemia (ALL), 14 patients with mature B cell neoplasm (10 non-Hodgkin's lymphomas [NHL], and four chronic lymphocytic leukemias [CLL]), 21 patients with T cell neoplasm (two ALL, eight NHL, nine CLL and two adult T cell leukemias), three patients with unclassified ALL, and 16 patients with acute nonlymphocytic leukemia were studied. Mononuclear cells were separated from heparinized peripheral blood or bone marrow by Ficoll-Hypaque density gradient centrifugation, or single-cell suspensions of lymph nodes were obtained from these patients, either at the time of diagnosis or relapse. The specimens of bone marrow, peripheral blood, and lymph nodes were gathered after informed consent was obtained according to the guidelines of the Kumamoto University Medical School Committee for Protection of Human Subjects.

Phenotypic analysis. Surface Ig (sIg) and cytoplasmic Ig (cIg) were detected with fluorescein isothiocyanate-conjugated goat anti-human polyvalent Ig, μ , γ , κ , and λ chains. The expression of common ALL antigen, B, T, and myeloid cell-associated antigen was determined by indirect immunofluorescence using a panel of murine monoclonal antibodies (mAbs): J5 (CD10), B4 (CD19), B1 (CD20), OKT3 (CD3), OKT4 (CD4), OKT6 (CD1), OKT8 (CD8), OKT11 (CD2), Tp40 (CD7), MCS-1 (CDw15), MCS-2 (CDw13), and antiplatelet glycoprotein IIb/IIIa complex.

Southern hybridization analysis.¹¹ Ten micrograms of DNA extracted from mononuclear cells were digested with an appropriate restriction enzyme, size-fractionated by 0.7% agarose gel electrophoresis, and transferred to a nitrocellulose filter. Filter-bound DNA fragments were then hybridized to nick-translated ³²P-labeled probes, washed with appropriate stringency, and visualized on autoradiograms. Rearrangements of the $T\gamma$ gene were examined with a 0.7-kilobase (kb) germline *Hind*III-to-*Eco*RI fragment containing the first J region (J γ 1) of the human $T\gamma$ gene, which was highly homologous with the second J region (J γ 2).⁷

RESULTS

The results of the Southern hybridization analysis with the JH, $T\beta$, and $T\gamma$ gene probes are summarized in Table 1, and representative autoradiograms are shown in Fig 1. The J γ 1 and J γ 2 genes exhibit rearrangement when DNA is digested with *Eco*RI⁹ or *Hind*III.⁷ Cells displaying the germline $T\gamma$

Nonlymphoid	16	16							

gene with *Eco*RI-digested DNA show either two 2.2-kb *Hind*III restriction fragments containing the J γ 1 and J γ 2 genes or this fragment together with a 5.2-kb fragment containing the J γ 2 gene. This is considered to reflect the existence of a nonallelic polymorphic fragment without a *Hind*III site corresponding to the 5' end of the J γ 2 gene, as previously described by Lefranc and Rabbitts.⁷ The results obtained with *Eco*RI-(Fig 1A) and *Hind*III-digested DNA (Fig 1B) hybridizing to the J γ 1 probe were identical except for the aforementioned polymorphic bands, thereby indicating that these rearrangements could not be ascribed to a restriction fragment length polymorphism. T γ gene rearrangements were detected in 19 of 21 cases of T cell neoplasm; 14 of 21 cases of immature B cell leukemia in which the cells expressed B4, J5, B1 antigen, or cIg but not sIg; none of 14 cases of B cell neoplasm in which the cells expressed a single Ig light-chain isotype, κ or λ ; all three cases of unclassified leukemia in which the cells reacted with neither myeloperoxidase staining nor B4, B1, Tp40, MCS-2, and antiplatelet IIb/IIIa mAb; and none of 16 cases of nonlymphoid leukemia. From 49 different rearranged T γ bands in 36 cases, only nine unique rearrangements were noted, which suggests that the diversity of human T γ genes produced by this recombination mechanism is more limited than that of the Ig or TCR genes.

DISCUSSION

T γ gene rearrangements were observed in 19 of 21 T cell neoplasms, 14 of 21 immature B cell leukemias, and all three unclassified leukemias. Thus, T γ gene rearrangement is not specific for T cells. Rearrangements of both JH and T β genes were also detected in immature B cells from five of 21 patients with ALL, as reported in previous papers.^{4,5,12} It is unlikely that these neoplasms are composed of a biclonal mixture of B and T cells because these neoplastic cells retained a pure immature B cell phenotype. The possibility that bigenotypic cells represent a consequence of neoplastic transformation is also unlikely because of the presence of these cells during normal lymphocyte differentiation.¹³ Therefore, bigenotypic cells were considered to reflect either the differentiation stage at which a committed B or T cell retains the potential to switch to the other lineage or the presence of common molecular mechanisms in rearrangements of JH and T β genes.¹² These possibilities are supported by the existence of similar structural configurations¹⁴ and a common recombinase¹⁵ for the JH and T β genes. T γ gene rearrangements in immature B cells may also be explained by these mechanisms. In immature B cells, however, T γ gene rearrangements were more frequently observed than T β gene rearrangements. In mouse hybridomas derived from fetal liver and fetal thymus, T γ gene rearrangements were detected in the fetal liver cells as well as in the thymus, although T β and then TCR α chain (T α) gene rearrangements occurred primarily or exclusively in the thymus.¹⁶ Therefore, T γ gene rearrangements are suggested to occur at high frequency in early lymphocyte differentiation. On the other hand, none of 14 B cell neoplasms had T γ gene rearrangements, which suggests that immature B cells showing T γ gene rearrangements were blocked in further differentiation. This result is in disagreement with the report of Griesser et al¹⁰ who showed T γ gene rearrangements in six of seven B cell lymphomas. The reasons for the discrepancies between our results and theirs are not clear. Furthermore, none of 16 nonlymphoid leukemias had T γ gene rearrangements. Although the function of the T γ gene product remains unknown, T γ mRNA expression in mice is specifically the highest early in thymic ontogeny and declines thereafter, which suggests that the putative T γ polypeptide plays a role for early T cell differentiation in the thymus.^{16,17} Therefore, functional T γ gene rearrangement and expression may be associated with T cell commitment and involved in the activation of T β gene rearrangement in the same way that productive Ig heavy-chain gene rearrangement activates κ light-chain gene rearrangement.³ This hypothesis is supported by the result that cells from four of five immature B cell leukemias displaying T β gene rearrangement also exhibited T γ gene rearrangement.

Fig 1. Southern blotting hybridization of the J γ 1 probe to *Eco*RI-(a) or *Hind*III-digested DNA (b) from hematologic neoplasms. Lane 1: DNA of HL-60 cells served as a control for the germline configuration. Lanes 2 through 7: DNAs prepared from immature B cell ALLs. Lane 8: T cell ALL. Lanes 9 and 10: unclassified ALL. DNAs from the same patients are in identical lane numbers in a and b. Dashes indicate the germline 3.5-kb and 1.5-kb *Eco*RI fragments containing the J γ 2 and J γ 1 genes, respectively, and show the two 2.2-kb *Hind*III fragments containing the J γ 1 and J γ 2 genes and a 5.2-kb *Hind*III fragment corresponding to the nonallelic polymorphic fragment of the J γ 2 gene. Arrows on the left of each lane indicate rearranged bands.

However, T γ gene rearrangement was not always found in T cell neoplasms that had T β gene rearrangements; in two of 21 T cell neoplasms, the T γ gene had the germline configuration. This is in contrast with previous reports⁷⁻¹⁰ that T γ gene rearrangements had been found in all cases of T cell neoplasms showing T β gene rearrangements. One possible explanation for our results is that a novel J region of the T γ gene, which is not highly homologous with the J γ 1 or J γ 2 region and does not hybridize to the J γ 1 probe, is used in V-J joining in such T cells. However, Lefranc and Rabbitts⁷ observed T γ gene rearrangements in all 16 T cell lines and 16 cases of fresh T cell leukemia tested using the J γ 1 probe. Quertermous et al⁹ also detected T γ gene rearrangement using the J γ 2 probe in all nine T cell lines and nine T cell neoplasms. Our findings indicate that T γ gene rearrangement and expression may not always be necessary for differentiation and antigen-specific functions of small numbers of T cells.

On the other hand, T γ gene rearrangement associated with the germline JH and T β genes was observed in one unclassified neoplasm as well as in two cases of Ki 1⁺ lymphoma reported by Griesser et al.¹⁰ We also detected this genotype in two cases of NHL (unpublished observation, August 1986). The existence of this novel T cell subgroup is

supported by the findings of Brenner et al¹⁸ who have reported that a small number of normal T3⁺ cells were WT-31⁻, which reacts with a common epitope of human TCR $\alpha\beta$ chains, and expressed T γ mRNA but not TCR $\alpha\beta$ mRNA, although most T3⁺ cells were WT-31⁺ and expressed TCR $\alpha\beta$ and T γ mRNA.

Consequently, T γ gene rearrangement is not specific for T cells and not always found in T cells but is largely restricted within lymphoid cells. Furthermore, the existence of cells showing T γ gene rearrangement but with the germline configuration of the JH and T β genes was demonstrated. Therefore, an analysis of T γ gene rearrangement provides a further potential tool for establishing the lymphoid cellular origin and clonality of hematologic neoplasms. Such studies would be useful not only in the diagnosis and evaluation of the clinical features and prognosis of patients with lymphoid neoplasm but also as a framework to identify normal stages of lymphocyte differentiation.

ACKNOWLEDGMENT

We are grateful to Drs T.H. Rabbitts and H. Sakano for providing probes of human immunoglobulin heavy-chain and T cell γ genes and a probe of the human T cell receptor β chain gene, respectively.

CONCISE REPORT

bcr-abl RNA in Patients With Chronic Myelogenous Leukemia

By E. Shtivelman, R.P. Gale, O. Dreazen, A. Berrebi, R. Zaizov, I. Kubonishi, I. Miyoshi, and E. Canaani

The major consequence of the formation of the Philadelphia (Ph¹) chromosome characteristic of leukemia cells of patients with chronic myelogenous leukemia (CML) is fusion of *c-abl* and *bcr* genes. Using a sensitive RNase protection technique, we analyzed mRNA from a large number of CML patients. In most, we identified one or both species of *bcr-abl* chimeric transcripts. These two mRNAs

vary in the specific *bcr* exon joined to *abl* exon II and are translated into slightly different proteins. The amounts of the fused mRNA within leukemia cells vary considerably between individuals and do not correlate with the phase of the disease.

© 1987 by Grune & Stratton, Inc.

CHRONIC MYELOGENOUS LEUKEMIA (CML) is characterized by two major phases. The chronic phase lasts an average of 3 years and is characterized primarily by accumulation of granulocytes and their precursors in the bone marrow and peripheral blood. This is followed by the acute phase (blast crisis) in which the leukemia cells fail to differentiate and to respond to regulatory factors of myelopoiesis. In some patients there is an intermediate accelerated phase.¹

A specific chromosomal abnormality, the Philadelphia chromosome (Ph¹), is present in 90% to 95% of CML patients.² This aberration results from a reciprocal translocation between chromosomes 9 and 22 designated t(9;22).³ Recent molecular studies implicate the *abl* oncogene and the *bcr* gene in CML. As a result of the translocation, *abl* is moved from chromosome 9 into the *bcr* gene on chromosome 22.⁴ The fused *bcr-abl* gene is transcribed into a large chimeric RNA which presumably initiates at the *bcr* promoter and is composed of *bcr* sequences 5' of the translocation point on chromosome 22 and sequences of chromosome 9 including *abl*, located downstream of the translocation point.^{5,6} The primary transcript is spliced into a mature *bcr-abl* mRNA of 8 kb.^{7,8,9} This mRNA is translated into a 210-kd protein unique to CML cells,^{10,11} and possessing enhanced tyrosine kinase activity compared to the normal *abl* protein.¹²

In a previous study⁵ we reported that in the 8-kb RNAs of two CML cell lines (K562 and EM2) the junction point is composed of *abl* exon II and *bcr* exon "3" sequences. We now sought to characterize the RNA junction in CML patients. In addition, we inquired whether the transition from the chronic to the acute phase of the disease involves increased transcription of the fused *bcr-abl* gene.

MATERIALS AND METHODS

Leukemia cells were isolated from the buffy coat of peripheral blood. RNA was prepared using the urea/lithium chloride method.¹³ Polyadenylated messenger RNA was isolated by purification on oligo-dT-cellulose columns. RNase protection analysis for the alternative *bcr-abl* junctions has been described.¹⁴ RNA probes were synthesized by standard techniques.¹⁵

RESULTS

For qualitative and quantitative analyses of *bcr-abl* RNA junctions in CML patients, we used the RNase protection technique. For probes we used two different junctions derived from cDNA clones K-28 and L-6. In the K-28 clone *abl* exon II is joined to *bcr* exon "3"; in L-6, *abl* exon II is

linked to *bcr* exon "2" (enumeration of *bcr* exons is according to ref 16). The positions of the relevant *abl* and *bcr* exons on the Philadelphia chromosome are shown in Fig 1, and the structure of the two probes is shown in Fig 2. RNAs of CML patients were annealed to each of the two probes and following RNase digestion were electrophoretically analyzed. Examples of these analyses are shown in Fig 2. For example, RNA from patient S-15 (Fig 2A, lane 1) protected the full-length 450-b K-28 probe. This indicates that within the 8-kb RNA of this patient, *abl* exon II is linked to *bcr* exon "3". The additional bands apparent in the autoradiogram result from protection of the 278-b *abl* segment within the probe by normal *abl* RNA, and from protection of the 172-b *bcr* DNA in the probe by normal *bcr* RNA. Hybridization of the L-6 probe to RNA from patient 1380 (Fig 2B, lane 1) resulted in protection of the 280-b probe. This implies that the *bcr-abl* RNA junction of this patient is composed of *abl* exon II and *bcr* exon "2" sequences. Bands of 250 and 255 b seen in this experiment represent protection of segments of the probe by normal *abl* RNAs containing alternative first exons.¹⁴

Results of analyses of samples from 21 CML patients are shown in Table 1. RNAs of 19 patients contained one or both RNA junctions. In two patients with Ph¹ chromosome we could not detect either junction. Seven patients had only the K-28 junction, and four only the L-6 linkage. Surprisingly, eight patients showed both junctions.

We next questioned whether the progression of the disease

*Relative amount of fused *bcr-abl* RNA ranked in a scale of 1 to 10 by signal intensity.

†No signal detected.

from chronic to acute phase is associated with enhanced synthesis of the fused *bcr-abl* RNA. We compared the signal intensity of the 450-b K-28 probe protected by RNAs from two patients in chronic phase (Fig 2A, lanes 1 and 2) and by RNAs from three patients in acute phase (blast crisis) (Fig 2A, lanes 3, 4, and 5). No correlation between signal intensity and disease phase was detected. Moreover, samples from the same patient taken during both phases of the disease contained similar amounts of the fused RNA (Fig 2A, lanes 6 and 7). Similar analyses were performed with RNA samples from patients with only the L-6 junction (Fig 2B). Again, we observed variability in the amounts of the fused RNAs and lack of correlation with disease stage. Quantitative results of these analyses are shown in Table 1.

DISCUSSION

In this study we demonstrate that RNA from 19 of 21 CML patients contain one or both of two alternative *bcr-abl* RNA junctions transcribed from the chimeric *bcr-abl* gene formed on the Ph¹-chromosome. In two patients with the Ph¹-chromosome, neither junction was detected. Levels in these individuals may have been below detection. Alternatively, these individuals may have fused RNAs in which different *abl* and *bcr* exons constitute the junction point. The resolution of which *bcr* exon will constitute the RNA junction point is most simply determined by the position of the t(9;22) translocation point on chromosome 22. Thus, if the breakpoint is between *bcr* exons "3" and "4," *abl* exon II will be linked to *bcr* exon "3." If the breakpoint occurs between *bcr* exons "2" and "3," the RNA junction point will be derived from *abl* exon II and *bcr* exon "2" (Fig 1). The

surprising finding that a large proportion of patients contain both RNA junctions probably represents alternative RNA splicing; when the breakpoint is between *bcr* exons "3" and "4," *abl* exon II can alternatively splice to *bcr* exons "3" and "2" (and possibly to other upstream *bcr* exons) to give two different RNA junctions (Fig 1). The two RNAs produced will be translated into proteins which vary in the 25 amino acid peptide coded by *bcr* exon "3."¹⁶ Whether the two proteins possess different biological activity is unknown. Interestingly, the breakpoint in 15 of 19 (79%) cases occurred between *bcr* exons "3" and "4".

In the second part of this work we showed that the amount of *bcr-abl* mRNA varies considerably between patients. Moreover, cells from patients in the acute phase do not contain, on average, higher levels of the fused *bcr-abl*

transcript. On the basis of these data, we conclude that transition from chronic to acute phase of CML is not the result of increased expression of the *bcr-abl* gene. Our studies do not exclude qualitative and quantitative alterations in the fused protein during phase transition. However, it is likely that other genetic changes, such as those associated with the additional chromosomal alterations typical of CML in acute phase,¹⁷ underlie the phase transition of the disease.

CORRESPONDENCE

COBALAMIN-FOLATE INTERRELATIONS

To the Editor:

I would like to comment on two points made by Dr Chanarin and his colleagues in their critical and comprehensive review of cobalamin-folate interrelations.¹

First, they state that "megaloblastic erythropoiesis is unique to humans." They have overlooked completely the classic writings of Marston, who in 1952 described a profound macrocytic anemia in which the oxygen-carrying capacity fell to 30% or lower in sheep suffering from cobalt deficiency.² Two further features were subsequently added to the picture: (1) the presence of abnormal primitive erythroblasts in the peripheral blood and (2) a spectacular response to folic acid. These were observed both in sheep reared on cobalt-deficient pastures and in experimental sheep rendered vitamin B₁₂ deficient under carefully controlled laboratory conditions. In these animals "the blood picture proclaims a disorder of bone marrow very similar to that which is evident in pernicious anemia and like the latter responds dramatically to folic acid."³ In a further publication Marston described the anemia as megaloblastic and noted that it responds equally dramatically to vitamin B₁₂ as well as to folic acid.⁴ True, the sheep is not the ideal experimental animal in which to study megaloblastic anemia because in it the effects of adenocobalamin deficiency are usually much more profound than those of methylcobalamin deficiency. It succumbs to the former usually before any serious degree of anemia develops.

Second, the authors state that "there is an unconfirmed report of increased urinary excretion of methylmalonic acid in patients anesthetized with N₂O."⁵ Other important substances are metabolized along the propionyl-succinyl pathway. Notable among these are valine and isoleucine. Dietary loading with both these amino acids will increase the methylmalonic aciduria in untreated pernicious anemia, indicating that their metabolism also is impaired at the methylmalonyl-CoA mutase block.^{6,7} This is true also in patients under nitrous oxide anesthesia. Serum valine levels were significantly elevated in patients anesthetized with nitrous oxide for periods of three hours or longer. This was attributed to the inactivation of adenosylcobalamin by nitrous oxide, thereby inducing the methylmalonyl-CoA mutase block with resulting accumulation of valine in the blood.^{8,9} The urinary excretion of methylmalonic acid was not increased in these patients (unpublished observation). Isoleucine, which is only partly metabolized along the propionyl-succinyl pathway, as well as valine, and partly along a vitamin B₁₂ independent ketogenic pathway, can also be elevated in patients undergoing nitrous oxide anesthesia, but the serum levels of both these amino acids show a pronounced fall in patients anesthetised without nitrous oxide.¹⁰ Three metabolites, valine, isoleucine, and methylmalonic acid, therefore accumulate proximal to the methylmalonyl-CoA mutase block in humans exposed to nitrous oxide.

This is convincing evidence that, unlike in the rat, the enzyme methylmalonyl-CoA mutase is inactivated by nitrous oxide in man. The serum valine levels measured by the highly sensitive microbiological method employed¹¹ (mean recovery 99.4%, coefficient of variation $\pm 3.2\%$ in 12 experiments after adding 4.0 mg % of L-valine to normal serum) would appear to be a more sensitive indicator of the mutase activity than the urinary methylmalonic acid under these very short periods of exposure to nitrous oxide.

To the Editor:

In response to Dr T.E. Parry, the anemia in sheep reared on cobalt-deficient feed and hence developing cobalamin deficiency when examined by hematologists was reported to be normocytic and normochromic,¹ and the marrow was hypoplastic.² The assumption 30 years ago that the anemia in sheep was megaloblastic was not based on any supporting evidence.

We are not aware of any convincing evidence for the inactivation

of methylmalonyl-CoA mutase by short-term exposure to nitrous oxide in man.

CLONAL ORIGIN OF ERYTHROID CELLS IN JUVENILE CHRONIC MYELOGENOUS LEUKEMIA

To the Editor:

We read with interest the article "Juvenile Chronic Myelogenous Leukemia: Characterization of the Disease Using Cell Cultures" by Estrov et al that appeared in a recent issue of this journal.¹

Our observations with an *in vitro* progenitor cell assay in two patients with juvenile chronic myelogenous leukemia (JCML) led us to different conclusions. Namely, the erythroid cells in this disease also descend from the leukemic clone. The erythroid cells from our patients proliferated *in vitro* and formed BFU-E colonies that could not be morphologically distinguished from BFU-E colonies of normal marrows, but they exhibited the karyotype of the leukemic clone. Thus JCML appears to be a multipotent stem cell disease like the Philadelphia chromosome-positive CML. Sato et al² also alluded to the fact that their observations of JCML suggested the pluripotent stem cell origin of JCML.

In our patients (see Table 1 for the summary of our clinical and laboratory findings), the bone marrow and blood specimens formed erythroid colonies. We used the culture method described by Ogawa et al³ for erythroid colonies in case 1 and the CFU-GEMM culture method described by Messner and Fauser⁴ with some modification in case 2. The modification consisted of using 30% plasma-derived horse serum (Sterile Systems, Inc., Logan, UT) and conditioned medium derived from culture of the human bladder carcinoma cell line 5637⁵ instead of human plasma and phytohemagglutinin LCM, respectively.

In case 2, the initial fresh marrow sample yielded two cytogenetically distinct clones, one with 45,XY,-7 (29 of 32 cells) and the

other, 46,XY (three of 32 cells). The results of CFU-GM and CFU-GEMM cultures are shown in Table 1. We cytogenetically examined pooled colonies that formed in the plate from the CFU-GEMM culture. Of 75 metaphases analyzed, 73 were 45,-7. One was 46,XY, and the other had 90 chromosomes. The blood cells cultured with phytohemagglutinin for three days yielded only the normal karyotype (26 metaphases examined). After the patient received one course of daily VP-16 and cyclophosphamide for five days, a blood sample was again cultured for CFU-GEMM. The sample formed an average of 221 colonies (duplicate plates) consisting of 43 erythroid, 33.5 mixed erythroid and granulocyte-macrophage, 98.5 pure macrophage, and 46 granulocyte-macrophage. The granulocyte or macrophage differentiation was confirmed by naphthol-ASD chloroacetate and α -naphthyl acetate esterase stains using Sigma cytochemical kits (catalogue no. 90-C2 and 90 A-1, Sigma Chemical Co, St Louis). All colonies formed in one dish were pooled and prepared for cytogenetic analysis. Separately, well hemoglobinized erythroid colonies from another dish were picked, pooled, and prepared for cytogenetic analysis. Both preparations yielded only metaphases with 45,XY,-7 (15 metaphases were examined from each preparation). The results strongly suggested that the erythroid cells derived from the leukemic clone proliferated *in vitro*. Since the erythroid colonies did not grow in the absence of erythropoietin, their growth appeared to be under the erythropoietin control.

Growth of erythroid colonies from bone marrow cells from a JCML patient has been described.⁶ Investigations of erythroid cells in this disease suggested a number of fetal characteristics such as a high fetal hemoglobin concentration and a prevalence of decreased

Abbreviation: ND, not done.

red cell I antigen.^{6,7} Whether this is an indication of the malignant erythroid clone or an epiphenomenon is unknown.

We are uncertain regarding the reasons for the discordant results of ours and those of Estrov et al.

Neither of our patients exhibited a high fetal hemoglobin concentration. It is possible that the high fetal hemoglobin variety may be a disease different from JCML without a high fetal hemoglobin content. This could be answered by culturing marrow and blood cells from patients with and without high fetal hemoglobin concentrations.

To the Editor:

The letter by Inoue et al provides further insight into the disordered hematopoiesis that characterizes juvenile chronic myelogenous leukemia (JCML). The relevant data are confined to the cytogenetic analysis of the plucked, well-hemoglobinized BFU-E erythroid colonies derived from cultures of the peripheral blood of case 2. The investigators demonstrated nicely that 15 erythroid cells in metaphase at the time of study showed monosomy 7, thus indicating their derivation from the leukemic clone. This does not prove that all of erythropoiesis in vivo and in vitro in case 2 was derived from the malignant clone because not all the BFU-E colonies were plucked for study and not all of the colonies that were selected were composed of cells in metaphase. Nevertheless, the data are important because they identify the leukemic "event" in case 2 at an early point in hematopoiesis, possibly at the level of the pluripotent stem cell similar to Philadelphia chromosome + adult CML.

As Inoue et al indicate, the cell culture findings from both of their patients at diagnosis were different than those that we reported.¹ Using CFU-GEMM and CFU-C assay systems, marrow and peripheral blood from our patients at diagnosis yielded only monocyte-macrophage colonies. Most importantly, the excessive proliferation of these colonies persisted in cultures lacking both adherent cells and exogenous colony-stimulating activity. We regard this latter finding as a diagnostic hallmark of JCML.

Since our publication, we have performed serial CFU-GEMM studies on peripheral blood from two patients who became resistant

to chemotherapy and developed recurrent, aggressive JCML. Specimens from both of these patients still yielded monocyte-macrophage colonies but also large numbers of highly proliferative BFU-E colonies that continued to grow actively on replating in secondary cultures. Karyotypes on plucked BFU-E colonies from both cases were normal, whereas monocyte-macrophage colony karyotypes were abnormal. These results differ but do not contradict those of Inoue et al for the technical reasons stated before.

The emergence of in vitro erythropoiesis in our cases may indicate that cell culture profiles in JCML change with time, chemotherapy, or advancing disease. Since marrow from both patients of Inoue et al showed excessive numbers of blasts, they may have already been in a highly malignant phase of disease similar to our cases that yielded BFU-E colonies.

Ongoing serial studies by interested workers will hopefully provide an answer to this and other aspects of JCML.

ERRATUM

In the article by Pui et al entitled "Shifts in Blast Cell Phenotype and Karyotype at Relapse of Childhood Lymphoblastic Leukemia," which appeared in the December 1986 issue, a typesetting error was made in Table 3. The partial karyotype in column 1 for Case 1 is repetitious and should be ignored.

ANNOUNCEMENTS

AMERICAN BOARD OF INTERNAL MEDICINE 1987 SUBSPECIALTY EXAMINATIONS IN MEDICAL ONCOLOGY AND CRITICAL CARE MEDICINE

Registration Period: January 1, 1987 through April 1, 1987
Examination Date: November 10, 1987

For information and applications forms, please contact: Registration Section, American Board of Internal Medicine, 3624 Market Street, Philadelphia, PA 19104.

LEUKEMIA SOCIETY OF AMERICA THIRD ANNUAL NATIONAL SYMPOSIUM

**Town and Country Hotel, San Diego, CA
March 18-21, 1987**

Designed to focus on the latest advances and techniques in research and treatment of leukemias and lymphomas, the program will address current information and rapidly developing new approaches and programs in studies of the disease. Emphasis will be upon the application of basic science and its relation to clinical practice. The meeting is geared to physicians, nurses, allied professionals, fellows-in-training, residents, and students with major interest and involvement in leukemia and related disorders. The course is accredited for CME by the AACME. It meets the criteria for 17 credits in Category I towards the Physician's Recognition of the AMA. Registered nurses will qualify for 20.7 contact hours of continuing education through the LSA's provider accreditation for continuing education for registered nurses.

There will be: a keynote address on "Chromosomes, Genes, and Leukemia" by Peter C. Nowell, MD; Stohlmán Memorial Scholar papers; posters; and five minisymposia, dealing with biological characteristics of clinical trial designs, molecular genetics, application of molecular probes, antimyeloid monoclonal antibodies, and cellular response to growth factors. There will also be daily group breakfasts and an awards banquet. Registration fee: physicians: \$100; nurses, fellows-in-training, residents, and students: \$60. Fees are due by March 11, 1987.

For registration and additional information, contact: LSA Medical Conference, c/o Bostrom Corporation, 435 N Michigan Ave, Suite 1717, Chicago, IL 60611. Telephone: (312) 644-0828.

21ST ANNUAL CONFERENCE ON PRACTICAL, CLINICAL, AND LABORATORY ASPECTS OF BLOOD COAGULATION

April 27-29, 1987

5TH ANNUAL ANTIBODY, SPECIAL COAGULATION, AND PLATELET TECHNIQUES WORKSHOP

April 25-26, 1987

Kellogg Center, Michigan State University

Sponsored by the College of Human Medicine, Michigan State University

Course Director: Dr John A. Penner

Workshop Director: Dr Houria I. Hassouna

For further information, contact: Mary Edna Helfer, Conferences, A118 E Fee Hall, Michigan State University, East Lansing, MI 48824-1022. Telephone: (517) 353-8856.

SYMPOSIUM ON PLASMA CELL MYELOMA AND RELATED DISEASES**April 10, 1987****Duke University Medical Center, Durham, NC****GUEST SPEAKERS**Daniel E. Bergsagel, *Toronto*M. Robert Cooper, *Winston-Salem*Brian G.M. Durie, *Tucson*Thomas A. Waldmann, *Bethesda*T.J. McElwain, *London*Howard Ozer, *Chapel Hill*

This symposium is sponsored by the Hematology/Oncology Division of the Department of Medicine. The natural history, clinical presentation, and evolution of plasma cell myeloma will be reviewed along with staging, treatment, and prognosis using standard regimens. The investigational use of high-dose melphalan chemotherapy and the interferons will be reported, and current investigations regarding the molecular biology of B cell neoplasms. Particular attention will be given to problems and complications encountered in patients with plasma cell myeloma and controversies in treatment. *For further information, write:* Myeloma Symposium, Box 3096, Duke Medical Center, Durham, NC 27710.

DR H. DUBOIS-FERRIÈRE—DINU LIPATTI RESEARCH FELLOWSHIP IN HEMATOLOGY

The Dr H. Dubois-Ferrière—Dinu Lipatti Foundation offers a research fellowship to a medical graduate with at least two years' experience in research. The recipient of the fellowship will have the opportunity to spend two or three years working on a hematology research program in Geneva. The annual stipend ranges from US \$30,000 to \$35,000.

For further information, contact: Fondation Dr H. Dubois-Ferrière—Dinu Lipatti, case postale 225, CH-1227 Carouge-Genève, Switzerland.

XIX MEETING OF THE INTERNATIONAL SOCIETY OF PEDIATRIC ONCOLOGY (SIOP)**September 13–18, 1987****Jerusalem Laromme Hotel, Jerusalem, Israel**

Deadline for abstracts: April 15, 1987

For further information, write: Prof R. Zaizov, PO Box 983, Jerusalem 91009, Israel.

5TH EUROPEAN CONFERENCE ON CLINICAL HEMORHEOLOGY**June 29–30 and July 1, 1987****Bordeaux, France**

The Presidents of the conference will be Prof P. Boivin and Prof J-F. Stoltz. The main topic will be the importance of blood methodology to clinical studies. There will be interdisciplinary sessions organized in collaboration with specialist societies for angiology, hematology, neurology, and thrombotic disorders.

For further information, contact: Prof Michel R. Boisseau, Secretariat Scientifique, Laboratoire d'Hématologie, Hôpital Cardiologique, Avenue Magellan, 33604 Pessac, France. Telephone: 56 36 24 45, extension 33148. Telex: 560 349 F.

NOW YOU CAN STORE LEUKOPOOR RED CELLS

...WITH THE CUTTER LEUKOTRAP™ RED CELL STORAGE SYSTEM.

Now you can cost-effectively produce and store high-quality leukopoor red cells for 42 days. The Leukotrap closed system efficiently removes leukocytes from fresh red cells, then maintains red cell viability for 42 days in the Nutricel® AS-3 additive solution.

MOST EFFICIENT CLOSED SYSTEM METHOD

The Leukotrap Storage System removes 91.4% of leukocytes and 80% of platelets, while recovering 90% of the red cells.*

Leukotrap's closed blood bag system contains an in-line leukocyte removal filter.

SIMPLE, RELIABLE PROCEDURE

The Leukotrap System provides consistent results with only minimal technician time and a standard centrifuge.

Provide a better red cell product with the Leukotrap Storage System...another Component Enhancement Product, only from Cutter.

For more information, contact your Cutter Biological Representative or call our Professional Services Department at (800) 227-1762.

The journal will publish the description, technical and clinical evaluation of specific molecules and cell lines which may be used in the diagnosis, location and monitoring of disease.

Also to be included are the description of new or greatly improved strategies for the production of molecules or cell lines potentially suitable as probes and of new strategies for the generation and detection of signals from such probes. Animal studies in so far as they are clearly relevant as models or tests of techniques applicable to man also come within the scope of the journal. The journal aims to cross the traditional boundaries of diagnostic and clinical medicine departments since new probes or new approaches to the development of probes are likely to be of interest to workers in a variety of fields outside that of the original discoverers. By the publication of new work and reviews the journal will aim to keep readers in close contact with the most recent advances in this rapidly expanding area of medicine.

Research Areas Include:

- Detection and measurement of specific molecules by polynucleotides, monoclonal antibodies and cloned hybridomas or cell lines.
- Improved strategies for the production of these probes.
- Improved methods for the generation or detection of signals from these probes *in vivo* or *in vitro*.
- Animal models used as tests of the probes.

Blenoxane *(sterile bleomycin sulfate)*

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma — Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas — Hodgkin's, reticulum cell sarcoma, lymphosarcoma.
Testicular Carcinoma — Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and

dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary — This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO}

falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

- (1) Maintain FI O₂ at concentrations approximately that of room air (25%) during surgery and the post-operative period.
- (2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions — In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes — These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other — Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate NDC 0015-3010-20.

POSTDOCTORAL FELLOWSHIP IN BLOODBANKING

LCGME approved, starting July 1, 1987 at the Hoxworth Blood Center of the University of Cincinnati, serving 30 hospitals and physically located in a Medical Center which includes the Medical School, the University Hospitals, Children's Hospital, and the VAH Medical Center. Special features include large crossmatching service, well-known reference laboratories and SBB-Masters immunohematology program; apheresis program; histocompatibility laboratories; kidney, heart, liver and bone marrow transplantation programs; active research program. Other educational activities include clinical rounds, seminars, journal club, and training of medical and technology students, pathology and hematology fellows and residents.

Respond by letter stating the reason for your interest in a career in blood banking and a complete curriculum vitae immediately to:

Tibor J. Greenwalt, M.D.
Director, Hoxworth Blood Center
Professor of Internal Medicine
University of Cincinnati
3231 Burnet Avenue
Cincinnati, Ohio 45267

RESEARCH SCIENTIST— CELLULAR IMMUNOLOGY/HEMATOLOGY

The Wadsworth Center for Laboratories and Research is seeking a research scientist with an interest in cellular immunology and hematology. The individual should have experience in flow cytometry and modern hematology instrumentation. The scientist will be encouraged to develop his/her own research interests, as well as to collaborate with other scientists to encourage developing cellular immunology and hematology research. The scientist will also have responsibilities for providing expertise in implementing appropriate proficiency testing programs in flow cytometry and hematology. There is a very definite commitment at the Wadsworth Center for support of innovative research of public health relevance. The candidate must have either a Ph.D., M.D., or D.V.M. with appropriate experience.

Please send CV and the names of three references to: Felix H. Heilpern, Wadsworth Center for Laboratories and Research, Empire State Plaza, Albany, NY 12201. An Affirmative Action/Equal Opportunity Employer.

NON-TENURE TRACK APPOINTMENT

Assistant Professor and Assistant Medical Director, University of Minnesota Hospital, Blood Bank, and St. Paul Region, American Red Cross Blood Services.

A position is available for a physician, Board certified or Board eligible in clinical pathology with blood banking fellowship or one year of experience in clinical pathology beyond residency. Alternatively, the candidate will be board certified in Internal Medicine or Pediatrics and board certified or board eligible in Hematology. Candidates should have experience in transfusion medicine and immunohematology.

This position will be involved in the teaching of blood banking/immunohematology through formal courses, informal supervision, and teaching of medical students, residents, fellows, and allied health students. This position will be expected to participate in basic or clinical research relating to one or more of the following areas: blood collection; platelet serology and transfusion; neutrophil structure, function or serology; apheresis; bone marrow donation or transplantation; histocompatibility; transfusion transmitted diseases; or other blood bank related topics.

This position will serve as Assistant Medical Director of the Regional Blood Services and the University Hospital Blood Bank and will assume partial responsibility for the daily operation of these facilities. This may include responsibility for the general blood bank laboratory.

This position is a temporary, non-tenure track faculty appointment which involves major service commitments. Applicants should send their curriculum vitae and three letters of recommendations to:

Richard Brunning, M.D.
Box 198 UMHC
Department of Laboratory Medicine and Pathology
University of Minnesota Hospital and Clinic
420 Delaware Street S.E.
Minneapolis, MN 55455

Deadline for receipt of applications is March 31, 1987. The University of Minnesota is an equal opportunity educator and employer and specifically invites and encourages applications from women and minorities.

**The New York Academy of Sciences
An International Organization
Conference On:**

**STRUCTURE AND ACTIVITIES OF HEPARIN AND
RELATED POLYSACCHARIDES**

**November 3-5, 1987
Vista International Hotel, New York City**

This conference will address the chemistry, biosynthesis, structure and functions of heparin, heparan sulfate and dermatan sulfate. It will address the potential clinical utility of these GAGs on the management of thromboembolic diseases. The current state of knowledge on the multiple regulatory functions of these glycosaminoglycans will be reviewed in a multidisciplinary manner. This conference also aims to highlight important unanswered questions on the biological effects of these glycosaminoglycans and should provide approaches to their resolution.

There will be a contributed poster session. The deadline for submission of abstracts is **June 1, 1987**. A 200-word summary of work to be presented should be sent to: **Frederick A. Ofsu, Ph.D., Department of Pathology, McMaster University, 1200 Main Street West, Hamilton, Ontario, Canada L8N 3Z5.**

Conference Chairs:

Frederick A. Ofsu, Ph.D., Department of Pathology

Jack Hirsh, M.D., Department of Medicine

McMaster University, Hamilton, Ontario, Canada
and

**Isidore Danishefsky, Ph.D., New York Medical College, Valhalla,
New York**

For program and registration information: Conference Department, The New York Academy of Sciences, 2 East 63rd Street, New York, NY 10021.

**ASSISTANT DIRECTOR,
BONE MARROW TRANSPLANT UNIT**

The Division of Hematology of the Department of Medicine, Stanford University School of Medicine, invites applications for Assistant Director of the newly formed Bone Marrow Transplant Unit. The position carries the rank of Assistant Professor of Medicine in the Division of Hematology. The faculty person will interact with clinicians and investigators in the Departments of Pediatrics, Pathology and Radiation Therapy, as well as the newly formed Center for Molecular and Genetic Medicine. Candidates should have experience and be expert in allogeneic and autologous Bone Marrow Transplantation. In addition, it is anticipated that the faculty person holding this position will devote approximately 60% of time to intensive work in the areas comprising transplantation biology. Thus, candidates should have demonstrated ability to develop an independent, self-sustaining research program.

Applicants should send a curriculum vitae, a brief statement of their research interests and names of two references to: **Stanley L. Schrier, M.D., Chief, Division of Hematology, Stanford University School of Medicine, Stanford, California 94305.**

Stanford University is committed to increasing representation of women and members of minority groups on its faculty and particularly encourages applications from such candidates.

**COOLEY'S
ANEMIA FOUNDATION, INC.
RESEARCH FELLOWSHIPS**

The Cooley's Anemia Foundation, Inc., invites applications for fellowships to both postdoctoral fellows and junior faculty members interested in the field of Cooley's anemia with stipends of up to \$15,000. The deadline for receipt of applications is April 1, 1987. Awards will be made by June 15, 1987, and funding will begin July 1, 1987, for one year with the possibility of renewal for a second year.

For application forms and further information, write: **Mr. Michael C. DiFilippo, National Executive Director, Cooley's Anemia Foundation, Inc., 105 East 22nd Street, Suite 911, New York, New York 10010. Telephone: (212) 598-0911.**

The Haemonetics Research Institute

**Announces the 12th International Apheresis
Symposium**

Sponsored by Haemonetics Corporation
and

E.I. du Pont de Nemours & Company

Cosponsored by the Postgraduate Medical Institute

April 27-28, 1987

**Loews L'Enfant Plaza Hotel
Washington, D.C. 20024**

Topics for discussion:

- Adoptive Immunotherapy Techniques
- Bone Marrow Processing and Transplantation
- Developments in Extracorporeal Therapy
- Platelet Collection and Transfusion
- Plasma Procurement
- Developments in Donor Testing

Haemonetics Operators Workshop

April 29, 1987

Conference Coordinator: Diane E. Etheridge

Haemonetics Corporation

400 Wood Road

Braintree, MA 02184

(617) 848-7100 ext. 291

The Postgraduate Medical Institute is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians.

The Postgraduate Medical Institute designates this continuing medical education activity for 13 credit hours in category 1 of the Physician's Recognition Award of the American Medical Association.

**CANADIAN RED CROSS SOCIETY
BLOOD TRANSFUSION SERVICE
OTTAWA CENTRE
DEPUTY MEDICAL DIRECTOR
POSITION**

The Ottawa Centre of the Canadian Red Cross Society, Blood Transfusion Service is inviting applications from physicians for the position of DEPUTY MEDICAL DIRECTOR.

The position involves major responsibility for a full service apheresis unit providing both cell support and plasma exchange services to a population of 800,000. The Deputy Medical Director participates in research and development programs and assists the Medical Director in general administration of the blood program. The Centre currently collects, tests, processes and issues approximately 65,000 units of blood annually.

Interested applicants should apply in confidence giving all details of experience and expected salary requirements to:

Dr. G. Rock
Medical Director
The Canadian Red Cross Society
Blood Transfusion Service
85 Plymouth Street
Ottawa, Ontario K1S 3E2

**Mammography
can detect
breast cancers
even smaller
than the hand
can feel.**

Low-dose breast x-ray, mammography, is giving hope that the leading cause of cancer deaths in women will be greatly diminished.

We urge women without symptoms of breast cancer, ages 35 to 39, to have one mammogram for the record, women 40 to 49 to have a mammogram every 1 to 2 years, and women 50 and over, one a year. Breast self-examination is also an important health habit and should be practiced monthly. Ask your local Cancer Society for free leaflets on both subjects.

The American Cancer Society wants you to know.

INTRODUCING FACScan™

*The flow cytometer
that fits in every lab*

There's room in every laboratory for FACScan.

FACScan takes a minimum of bench space, yet it delivers the performance of larger, more expensive instruments.

Like larger flow cytometers, FACScan uses an argon-ion laser for 5-parameter analysis.

Unlike larger instruments, FACScan plugs right in. You don't need an external compressed air or water supply.

FACScan is also easy to use. You can readily perform a variety of clinical research applications, including lymphocyte phenotyping, immune monitoring, DNA analysis, reticulocyte counting, and platelet studies.

Set up and operation are automatic with CONSORT™ 30 applications software. And you can even automate sample introduction with the FACS™ AutoMATE.

Of course, FACScan is supported by Becton Dickinson's complete line of Leu monoclonal reagents, training and applications specialists, and expert field service.

FACScan. The flow cytometer that fits in every lab.
